Abstract. The effect of adding carbon black on the electrical and rheological properties of graphite nanoplatelets/poly(ethylene-butyl acrylate) copolymer composites produced via melt or solution mixing was studied. By adding a small amount of low- or high-structured carbon black to the nanocomposite, the electrical percolation threshold decreased and the final conductivity (at higher filler contents) increased. The effect on the percolation threshold was significantly stronger in case of the high-structured carbon black where replacing 10 wt% of the total filler content with carbon black instead of graphite nanoplatelets reduced the electrical percolation threshold from 6.9 to 4.6 vol%. Finally, the solution mixing process was found to be more efficient leading to a lower percolation threshold. For the composites containing high-structured carbon black, graphite nanoplatelets and their hybrids there was a quite reasonable correlation between the electrical and rheological percolation thresholds.

Keywords: nanocomposites, hybrid composites, electrical properties, rheology, melt mixing

1. Introduction

Polymer nanocomposites combine the properties of the polymeric matrix with those of the filler. Traditionally carbon black (CB) has been the filler of choice due to the simplicity of its preparation methods that lead to low prices coupled with good overall performance [1]. The introduction of carbonaceous fillers into the polymer matrix can lead to electrical conductivity, whose level is tightly dependent on the type of filler and polymer used. Depending on the filler and the conductivity level required a large array of materials suited for electrochemical devices and other applications (e.g. fuel cells, batteries, supercapacitors, power cable shielding, auto-

motive boards, chemical vapor sensors, pipe applications etc.) can be designed [2, 3]. The conductivity level required for industrial applications varies, but can be quite high leading to an increase of the overall viscosity, thus leading to processing and performance problems [4].

High aspect ratio fillers based on carbon allotropes like graphene and carbon nanotubes (CNT) offer distinct advantages in comparison with more traditional fillers like carbon black mainly originating from their sheer size [5]. Ever since the first observations of graphene in 2004 [6], graphene-containing polymer nanocomposites have triggered a significant interest. A large number of research groups

have published a variety of results indicating superior electrical and thermal conductivity, mechanical and rheological properties, gas barrier properties and crystallization behavior of nanocomposites based on high aspect ratio carbon allotropes [5, 7–9].

Hybrid composites of mixtures between different carbonaceous fillers have been seen to exhibit synergistic effects. Fan *et al.* [10] noted a decrease of the percolation threshold and a higher electrical conductivity by combining CB with graphite nanoplatelets (GNP). Similar positive effects have been observed in carbon nanotube (CNT)/graphite nanoplatelet hybrids [11–13] and CNT/GNP/CB hybrids [14]. Furthermore, by combining CNT with CB or GNP the viscosity of the composite melt has been reported to decrease in comparison to single filler composite melt at the same filler loading [15]. This effect was observed already at a content of 1 wt% CNT.

Published results on GNP-CB hybrids are often based on thermosetting polymer systems and high-structured carbon black. With the term high-structured CB we are referring to systems made by fusion of the primary particles into an extended three dimensional structure. The overall dimensions and density of this structure (it can be chain or cluster-like) depend on the preparation method of the CB [16]. There is a need to further explore possible synergistic effects of these hybrids in thermoplastic polymers and study the effect of the CB structure. In the present work, the effects of adding low- and high-structured carbon black, on electrical and rheological properties of a composite based on GNP/poly(ethylene-butyl acrylate) copolymer (EBA) are reported. Different mixing methods are employed with the solvent processing route used as reference. Electrical conductivity and rheological properties were measured along with characterization of the composites using differential scanning calorimetry (DSC) and scanning electron microscopy (SEM). Hybridization of carbon fillers is particularly applicable to extruded materials, where nanoplatelets tend to orient, leading to a need to create conductive paths/bridges between the different filler particles as to maintain the integrity of the conductive network. Due to this fact and since extrusion is a major processing technique, the electrical conductivity measurements and the SEM studies were performed on extruded specimens.

2. Experimental

2.1. Materials

The polymer used was a poly(ethylene-butyl acrylate) random copolymer (EBA) with 17 wt% butyl acrylate (BA), MFR of 7 g/10 min at 190°C and a density of 0.925 g/cm³ (Borealis AB, Sweden).

A high-structured carbon black (HS-CB), Ketjenblack EC 600JD (AKZO Nobel, the Netherlands), with an aggregate size of 10–50 nm, density 1.8 g/cm³, BET surface area 1250 m²/g, according to the supplier, was used. Also a low-structured furnace carbon black (LS-CB) with a surface area of 100–200 m²/g and a density of 1.8 g/cm³ was used. The graphite nanoplatelets (GNP) used were xGnP M5 (XG Sciences, USA), with a thickness of 6–8 nm, diameter of 5 µm, density of 2.2 g/cm³ and surface area of 120–150 m²/g, as given by the manufacturer.

2.2. Compounding

A series of composites containing pure fillers and hybrids in which GNPs were combined with CB (both low- and high-structured) were manufactured. The hybrid compositions used were 90-10, 80-20 and 70-30 for the high-structured CB and 80-20, 70-30 and 60-40 for the low-structured CB. The first number in the hybrid composition denotes the wt% of GNP of the total filler content and the second the wt% of CB. The filler contents used were in the range of 0.5–6.5 volume-% (vol%) for the HS-CB system, 5–14 vol% for the GNP systems, 2–9 vol% for the HS-CB/GNP hybrids and 6–18 vol% for the LS-CB materials and its hybrids.

A Brabender mixing chamber, with a volume of 50 cm³, was used to compound the composites. The mixing was performed at 180°C at 100 rpm for 10 minutes.

Xylene (AnalaR Normapur, VWR Prolabo) was used in a solvent mixing technique. EBA and xylene, 1:15 weight concentration, were stirred at 120°C until the polymer was completely dissolved after 2 hours. GNP and xylene, 1:50 weight concentration, were first stirred at room temperature for 15 minutes, and then sonicated for 4 h in a Branson 1510 E-MTH bath (70 W), Branson Ultrasonic. Every 30 minutes the sonication was shortly stopped and the mixture was stirred for 1 minute. After sonication, the GNP-xylene mixture was heated and added to the EBA-xylene mixture and stirred for an additional 30 min-

utes. After the stirring, the solution was poured into wide bowls in order to evaporate the solvent overnight followed by a final drying in a vacuum oven at 70°C for 12 h. This mixing technique was only used for the high structured CB hybrids and the pure GNP at a filler content of 10 wt%.

2.3. Scanning electron microscopy (SEM)

Scanning electron micrographs were obtained using a low vacuum JSM-6610 LV from Jeol, Japan, with an acceleration voltage of 8 kV and a JSM-7800F from Jeol with an acceleration voltage of 3 kV. The specimens, taken from extruded strings, were ion polished, perpendicular to the flow direction, with a broad ion beam (Gatan Iliont model 693, USA) at 4 kV at –60°C, in order to obtain a smooth surface for SEM studies.

2.4. Differential scanning calorimetry (DSC)

For the DSC measurements, a TG-DTA/DSC STA 449 F1 Jupiter, Netzsch-Gerätebau GmbH, Germany, equipped with a thermocouple Type K, was used. The melting behavior was recorded during heating from 30–200°C under argon atmosphere at a heating rate of 10°C/min. Specimens were taken from extruded strings, similar to the ones used for the electrical measurements.

2.5. Electrical measurements

Electrical measurements were performed using the two-point technique [17]. The specimens were extruded in a capillary rheometer, Ceast Rheoscope 1000 6742/00, Ceast SpA, Pianezza, Italy, using a die with a length/diameter (L/D) ratio of 10/1 [mm/mm] at 170°C. A low piston speed, 2 mm/min, corresponding to a shear rate of 24.3 s^{–1}, as well as a higher piston speed, 20 mm/min (243 s^{–1}) were used, but only two of the systems were subjected to the higher shear rate. The extrudates were then cryo-fractured in liquid nitrogen to a length, l , of 2.5 cm and the fracture surfaces were painted with conductive silver paint. A voltage was applied over the length of the extrudate and the current was measured with a Fluke 8846A Digital multimeter and the resistance, R , was evaluated. The diameter of the extrudates were measured using a digital caliper and the cross section area, A , was calculated. The electrical conductivity, σ , could then be obtained from Equation (1):

$$\sigma = \frac{A}{Rl} \quad (1)$$

Three different voltage levels were used; 10 V for materials with a conductivity higher than 10^{–3} S/cm, 100 V for materials with a conductivity between 10^{–5} and 10^{–3} S/cm and 300 V for conductivities lower than 10^{–5} S/cm. For each system, ten specimens were employed, and the average values are reported. The standard deviation was below 20% for materials with conductivities higher than 10^{–3} S/cm and it then increased with decreasing conductivity. Since a two-point method was used one cannot fully exclude the existence of surface currents. This could to some extent affect the measured conductivity.

2.6. Rheological measurements

A stress-controlled rotational rheometer, Rheometrics SR200, was used at 180°C under N₂ atmosphere for evaluating the viscoelastic properties of the materials. A parallel plate fixture was employed into which compression molded discs, produced in Bucher press in a frame-like mold at 180°C and a total melting time of 10 minutes, with a diameter of 25 mm and a thickness of 2 mm were inserted. All measurements started with a dynamic time sweep conducted at 0.5 Hz using a low stress until stabilization of the storage modulus G' was attained, as suggested by Kim and Macosko [18, 19]. Dynamic stress sweeps were conducted in order to determine the limit of the linear viscoelastic region and dynamic frequency sweeps were then performed well below this limit from 10 Hz down to 0.002 Hz. For each system two or three measurements were performed and the average values are reported.

3. Results and discussion

3.1. Scanning electron micrographs

Figures 1, 2 and 3 show scanning electron micrographs of the extruded 80-20 hybrid based on GNP and HS-CB at a filler content 5.6 vol%. The micrographs were taken close to the surface of the extrudate. In Figure 1 it can be seen that needle-like GNP stacks were oriented in the flow direction and parallel to the surface of the extrudate. The existence of large needle-like agglomerates indicates poor mixing and that the effective surface area of the filler was decreased compared to the initial surface area. At a higher magnification, Figure 2, it is

evident that large agglomerates consist of thinner GNP platelets while thinner platelets with a thickness smaller than 50 nm were present in the material. At even higher magnification, Figure 3, platelets with a thickness smaller than 20 nm can be observed. Also in Figures 2 and 3, HS-CB particles can be

Figure 1. Scanning electron micrograph of the 80-20 GNP HS-CB hybrid at a magnification of 2000×

Figure 2. Scanning electron micrograph of the 80-20 GNP HS-CB hybrid at a magnification of 10 000×

Figure 3. Scanning electron micrograph of the 80-20 GNP HS-CB hybrid at a magnification of 25 000×

observed between the GNP-stacks homogenously dispersed in the matrix. It is expected that the well dispersed CB particles could provide a physical bridge between the GNP stacks.

An identical orientation effect was observed also in the pure extruded GNP composite, both melt and solvent mixed. No clear differences could be observed with regard to the agglomerate size between the different mixing methods. In the HS-CB composite a good level of dispersion was noted with only few smaller agglomerates present.

3.2. Thermal analysis

The DSC measurements did not indicate clear differences in the crystallinity of the composites as compared to the pure polymer. There was a slight tendency towards higher crystallinity for the materials containing GNP and a slightly lower crystallinity for the materials containing CB compared to the unfilled EBA. A slightly narrower melting endotherm for the composite materials, especially the GNP composites, was observed and indicates that the crystals were thinner than in the unfilled EBA, see Figure 4. This can be attributed to the spatial arrangement of the filler particles that limit the possibility of polymer crystallization, as a number of nucleating sites become available for crystallization initiation. The existence of these different nucleation sites has been reported to lead to a decrease in crystallization rate [20, 21] The reason for such behavior has been attributed to the two-dimensional nature of the GNP platelets that makes lattice matching the dominant force in the crystallization process. The polymer chains need to be absorbed on the graphitic surface and this will force them to undergo conformational changes that subsequently lead to longer crystal-

Figure 4. DSC thermograms for nanocomposites and matrix material

lization times. Furthermore, due to the flat surface available for crystallization the polymer crystals can grow at multiple points and with multiple orientations. It has been speculated that the growth of adjacent crystals under these conditions might cause interference between them, leading to the overall suppression of the crystallization kinetics [21]. A similar behavior has been observed with GNP in polypropylene by Kalaitzidou *et al.* [22].

3.3. Electrical conductivity

Figure 5 shows the electrical conductivity as a function of the filler volume fraction for the GNP, the high-structured CB and its hybrids. The onset of electrical conductivity for the CB system was found to be the lowest, just below 2.1 vol%, and the ‘pure’ GNP composite had the highest percolation threshold, just below 6.9 vol%. The conductivity corresponding to the plateau value approached at higher filler contents was several orders of magnitude higher for the CB composites than for those containing GNP. In the work of Strååt *et al.* [23] the same kind of CB was mixed with both polypropylene (PP) and high density polyethylene (HDPE) and despite the fact that both processing and electrical measurements were conducted in a similar manner as in the present work, they report a lower percolation threshold for both polymer systems, being of the order 1 vol%. The percolation threshold of 6.9 vol% (15 wt%) found in this work for the pure melt mixed GNP composite is rather low compared to published results. Polyolefins containing GNP have usually a rather high percolation threshold, e. g. between 12 and 15 wt% in linear low density polyethylene and 14–16 wt% in an ethylene-vinyl acetate copolymer, both prepared by

a solution mixing method which is more effective compared to melt-mixing [24, 25]. For polypropylene, a percolation threshold of 7 vol% has been found in a melt mixed material [26].

By replacing only 10 wt% of the total filler content with HS-CB instead of GNP, the electrical percolation was dramatically reduced, from 6.9 to 4.6 vol%, whereas the conductivity plateau above the threshold increased (Figure 5). The same effect was observed when larger amounts of the overall filler content were replaced with CB. The effect of hybridization with CB has been studied earlier by Fan *et al.* [10] in epoxy-based composites, where by replacing 10% of the total filler content (GNP) with a high-structured carbon black the conductivity increased three orders of magnitude compared to the case with GNP alone when the total filler content was 1 wt%. They also observed a decrease in the percolation threshold from 0.75 to 0.5 wt%. This effect can be attributed to the existence of conductive bridges between the individual GNP agglomerates created by the CB particles. The reasoning for this is that high-structured CB being smaller and of significantly lower aspect ratio than GNP has a tendency of dispersing in a more efficient manner. This dispersion can act like a physical bridge between the GNP-rich areas in the matrix while at the same time restricts their dispersion and reagglomeration (see Figure 2). In the work by Wei *et al.* [14] carbon nanotubes were introduced in a similar system resulting in a three-filler-hybrid composite, and an even lower percolation threshold of 0.2 wt% was reported. These effects were also attributed to the ability of the spherical CB particles and the long flexible CNTs to form effective links between the more rigid GNPs.

The orientation in the flow direction of the anisometric fillers will influence the electrical properties. An extended level of orientation of the platelets could be expected to result in a higher percolation threshold due to a decreased particle-particle interaction [5, 9]. Therefore it is expected that the extruded strands used in this study will exhibit a higher percolation threshold than the corresponding non-oriented composites. For the pure GNP system and the 80-20 hybrid a higher piston speed (20 mm/min) was used to enhance the orientation of the fillers. This increased the onset of electrical conductivity to approximately 7.4 and 4.7 vol%, respectively, and can be compared with the results for 2 mm/min where the onset was 6.9 and 4.2 vol%, respectively.

Figure 5. The electrical conductivity as a function of the filler content for composites containing GNP, HS-CB and hybrids. Solid lines represent fitting to the percolation theory Equation (2).

The experimental data was fitted to the classical percolation theory (Equation (2)):

$$\sigma = \kappa(\omega - \omega_c)^\beta \quad (2)$$

where σ is the conductivity of the composite, ω is the filler content, ω_c the filler content at the percolation threshold, κ and β are fitting parameters where κ is related to the conductivity of the filler and β is connected to the systems dimensionality [27]. Here it must be noted that Equation (2) is derived for ideal conditions where all filler particles are of equal size, not agglomerated and non-oriented.

The percolation behavior of the pure CB and GNP systems could be fitted to Equation (2) as shown in Figure 5. The hybrid systems could not be fitted due to the lack of a clear conductivity plateau at higher loadings resulting in an unrealistic high value of κ . The lack of conductivity plateau is believed to originate from the increasing amount of CB with increasing filler content.

The conductivity results for the low-structured CB, the pure GNP and their hybrids are shown in Figure 6. The pure CB-based composite was seen to have a higher percolation threshold (12.1 vol%) and conductivity plateau at high loadings than its GNP-based equivalent. In a similar study using poly(ethyl-vinyl acetate) copolymer as matrix, the higher level of the conductivity plateau for CB-based systems in comparison with the GNP-based ones was attributed to the extended agglomeration of the GNPs and the subsequent overall aspect ratio reduction [5]. The substantially higher percolation threshold of the LS-CB compared to the HS-CB is likely associated

with the much lower BET surface area of the former particles.

For the low-structured CB hybrids, the percolation threshold decreased when some of the GNP was replaced by CB, at least in the case of the 80-20 and 70-30 hybrids. In the 60-40 hybrid the percolation threshold is slightly higher compared to the pure GNP but the conductivity plateau was, as for the other hybrids, higher than for the pure GNP system. This latter behavior can be discussed in a similar manner as for the HS-CB systems. Even though the percolation threshold was higher for the LS-CB compared to the GNP, the CB particles were effective in the building up a conductive network by connecting the 2-dimensional oriented GNPs with each other. A synergistic effect, not as strong as in the HS-CB hybrids, was observed resulting in a decrease of the percolation threshold.

Figure 7 shows the electrical conductivity of the solvent-mixed materials as a function of the filler content. For the melt-mixed materials, the percolation threshold for the pure GNP systems was approximately 6.9 vol%. Here it must be noted that the 10 wt% (4.5 vol%) solution-mixed composition had similar conductivity as the 7.4 vol% melt-mixed composition indicating a significant decrease in the percolation threshold. The same pattern can be seen for the hybrid formulations where for example the solution-mixed 80-20 hybrid at 10 wt% (4.7 vol%) had similar conductivity level as the 7.7 vol% melt mixed composition. Based on these results, the solution-mixing process was more efficient in terms of filler dispersion in comparison with the melt-mixing one for this specific combination of polymer

Figure 6. The electrical conductivity as a function of the filler content for composites containing GNP, LS-CB and hybrids

Figure 7. The electrical conductivity for solvent-mixed composites based on GNP or GNP/HS-CB containing 10 wt% filler

Figure 8. Scanning electron micrograph of the solvent-mixed material containing 10 wt% GNP at a magnification of 1000×

and filler, something that has been seen in earlier works of many authors [26, 28–30]. In the work by Oxfall *et al.*, [28] GNP was mixed with polystyrene (PS), and it was observed that relatively large agglomerates were present in the composite after the melt mixing process. However when a solution-mixing method was employed, the number of large agglomerates was dramatically reduced resulting in a higher conductivity. In the present study, no differences could be discerned between the solvent and melt mixed systems with respect to the overall agglomerate size, see Figure 8. The decrease in percolation threshold observed when the solution-mixing method is used is thought to originate from the more efficient formation of thin graphite stacks [28]. Persson *et al.* [31] have shown that thin graphene stacks, consisting of mainly three layers and not more than five layers, are formed when employing solution mixing and these are likely to contribute to

Table 1. Electrical percolation thresholds for the different materials

System	Percolation threshold [vol%]	Piston speed at extrusion [mm/min]
GNP	$6.4 < \omega_c < 6.9$	2
GNP	$6.9 < \omega_c < 7.4$	20

GNP/LS-CB, 60-40	$6.9 < \omega_c < 7.5$	2

the lower percolation threshold in case of the equivalent systems observed in the present study.

Table 1 is a summary of the electrical percolation thresholds reported in this work and at which extrusion speeds the specimens were produced.

3.4. Rheological properties

Figures 9 and 10 show the storage modulus, G' , as a function of frequency for the systems containing GNP, high-structured CB. Typically, there is a correlation between the plateau of G' at the lower frequencies (solid-like response) and the onset of the electrical conductivity (see references [5, 7, 9 and 32] for further discussion). Another way of analyzing the rheological data is to find when G' becomes larger than the loss modulus G'' at low frequencies. This can also constitute a measure of the rheological percolation [33]. In the present work, the filler concentration where the cross-over between G' and G''

Figure 9. The storage modulus G' vs frequency for the GNP/EBA composites at different filler contents measured at 180°C

Figure 10. The storage modulus G' vs frequency for the HS-CB/EBA composites at different filler contents measured at 180°C

Figure 11. G' and G'' as a function of the filler content of the 80-20 hybrid containing GNP and HS-CB measured at 180°C

took place was evaluated assuming a linear dependence of the moduli as functions of the filler content. The moduli G' and G'' as function of filler content for the 80-20 hybrid are shown in Figure 11. Table 2 shows the filler content at which the cross-over of the two moduli occurs. It should be made clear that an exact relation between the rheological and the electrical percolations are not expected in this case since the two types of test specimens differ in the degree of orientation; i.e. the rheological studies were conducted with non-oriented melts whereas the conductivity was measured using extruded strands. However similar trends can be noted when comparing the results in Tables 1 and 2.

The filler content at which the cross-over occurred was significantly higher for the GNP-based composite in comparison with the HS-CB-based system. As shown in Table 2, even small amounts of the high-structured CB reduced the cross-over concentration significantly in case of the HS-CB based hybrids. In the case of the LS-CB systems the rheological percolation (for the same filler content) was observed to be of similar order to the one observed for the GNP-composite. Replacing some of the GNP with

the low structured CB actually produced an increase of the onset of rheological percolation.

Although it is not expected that there would be a very close agreement between the threshold values from the rheology and conductivity measurements, due to the orientation and possibly to the crystallization behavior, it is worthwhile to comment on this. First it can be noted that all composites exhibited a solid-like behavior at higher filler contents as manifested by the plateau in the storage modulus in the low frequency region. This can be associated with the formation of a filler network. The filler concentration at the G'/G'' cross-over was higher for the GNP composite (no CB) than the electrical percolation threshold, (Tables 1 and 2). In Figure 9 it can be seen that the flattening of G' at lower frequencies took place between 7.4 and 7.9 vol% which is in correspondence with the G'/G'' cross-over. In the case of the HS-CB, the G'/G'' cross-over concentration was lower than the electrical percolation threshold. The cross-over concentration corresponded again reasonably well with the flattening of G' at 1.6 vol% (Figure 10). Based on this we can see that the GNP and the HS-CB systems behave in an opposite manner when the different percolation thresholds are compared.

With increasing amounts of HS-CB in the hybrid systems, the rheological threshold shifted from above the electrical threshold below it for the 70-30 hybrid. The correlation between the two thresholds is quite reasonable for the HS-CB/GNP systems considering the difference in orientation between the specimens. Strååt *et al.* [23] reported a good agreement between the electrical and the rheological thresholds in the case of PP and PE containing the same type of high-structured CB as used in this study. The conductivity measurements reported in this case [23] were also performed using extruded strands.

For the LS-CB systems the correlation between the rheological and the electrical percolation was clearly poorer. In Figure 12, G' as a function of frequency is shown for the LS-CB/EBA materials and it is evident that the flattening of G' at lower frequencies started already at 7.1 vol% compared to the onset of electrical conductivity between 11.4 and 12 vol%. The G'/G'' cross-over indicated a similar low value of 7.3 vol%. The hybrids containing LS-CB exhibited, in similarity with the GNP/EBA material, a higher G'/G'' cross-over compared to the

Table 2. The filler content at the G'/G'' crossover (rheological percolation)

System	G'/G'' cross over [vol%]
GNP	7.4
HS-CB	1.5
GNP/HS-CB, 90-10	5.2
GNP/HS-CB, 80-20	3.8
GNP/HS-CB, 70-30	3.2
LS-CB	7.3
GNP/LS-CB, 80-20	8.3
GNP/LS-CB, 70-30	8.6
GNP/LS-CB, 60-40	8.1

Figure 12. The storage modulus G' vs frequency for the LS-CB EBA composites at different filler contents measured at 180°C

electrical percolation. The difference between the two decreased however with increasing amounts of LS-CB, (Table 2).

4. Conclusions

The effect of both low- and high-structured carbon black on the electrical and the rheological properties of graphite nanoplatelet/poly(ethylene-butyl acrylate) composite have been assessed. It was found that the presence of both high- and low-structured CB in the matrix lead to a decrease of the electrical percolation threshold, with the effect being more pronounced in the case of the high-structured carbon black. This synergistic effect has been attributed to the creation of conductive bridges between the two different fillers.

In the extruded specimens used for electrical measurements a significant orientation of the filler particles in the flow direction was observed. The orientation had a significant effect on the overall conductivity of the composites.

Both melt and solution mixing methods were employed when producing the composite materials and the solution-based systems are seen to exhibit lower percolation threshold than the melt-mixed ones. This was attributed to the enhanced dispersion that is achieved by the solution process.

The presence of CB and GNP in the matrix affects the overall morphology of the system leading to thinner crystals and slight changes in the degree of crystallinity, evident by the slightly narrower melting endotherm and the shifted melting point.

Even though two types of test specimens that differed in the degree of orientation were used for the electrical and rheological measurements similar

trends can be noted when comparing the electrical and rheological percolation thresholds. The composites containing high-structured carbon black, graphite nanoplatelets and their hybrids showed a quite reasonable correlation between the two types of percolation values. For the composites containing the low-structured carbon black, the correlation between the rheological and the electrical percolation thresholds was clearly poorer.
