## Abstract

We present the discovery of three small planets transiting K2-136 (LP 358 348, EPIC 247589423), a late K dwarf in the Hyades. The planets have orbital periods of  $7.9757 \pm 0.0011$ ,  $17.3068^{+0.00034}_{-0.00036}$ , and  $25.5715^{+0.0038}_{-0.0040}$  days, and radii of  $1.05 \pm 0.16$ ,  $3.14 \pm 0.36$ , and  $1.55^{+0.24}_{-0.21} R_{\oplus}$ , respectively. With an age of 600–800 Myr, these planets are some of the smallest and youngest transiting planets known. Due to the relatively bright ( $J = 9.1$ ) host star, the planets are compelling targets for future characterization via radial velocity mass measurements and transmission spectroscopy. As the first known star with multiple transiting planets in a cluster, the system should be helpful for testing theories of planet formation and migration.

**Key words:** planetary systems – planets and satellites: detection – stars: individual (LP 358-348) – techniques: photometric – techniques: spectroscopic

## 1. Introduction

The NASA *K2* mission (Howell et al. 2014) is continuing the legacy of *Kepler* by conducting high precision time-series photometry of stars in the ecliptic plane, leading to the discovery of many new transiting planets (see, e.g., Crossfield et al. 2015; Montet et al. 2015; Petigura et al. 2015; Sanchis-Ojeda et al. 2015; Vanderburg et al. 2015, 2016a, 2016b; Hirano et al. 2016; Schlieder et al. 2016; Van Eylen et al. 2016; Fridlund et al. 2017; Guenther et al. 2017; Hirano et al. 2017; Smith et al. 2017). Besides revealing planets around brighter and lower-mass stars (Crossfield et al. 2016), *K2* is enabling a wider survey across different stellar environments, including several nearby open clusters. The ages of cluster stars are usually known with much better accuracy than field stars. By detecting and characterizing planets in clusters, we may thereby observe how planets and their orbits evolve in time.

To date, radial velocity (RV) and transit surveys have uncovered only a relatively small number of planets in clusters: in Taurus-Auriga (Donati et al. 2016), NGC 6811 (Meibom et al. 2013), NGC 2423 (Lovis & Mayor 2007), M67 (Brucalassi et al. 2014, 2016), Upper Scorpius (David et al. 2016b; Mann et al. 2016b), Pleiades (Gaidos et al. 2017), Praesepe (Quinn et al. 2012; Malavolta et al. 2016; Obermeier et al. 2016; Mann et al. 2017; Pepper et al. 2017), and Hyades (Sato et al. 2007; Quinn et al. 2014; David et al. 2016a; Mann et al. 2016a). Of these, the most favorable targets for future study are those transiting stars bright enough for Doppler mass measurement and atmospheric transmission spectroscopy to be feasible.

Here, we report on the first known transiting multi-planet system in a cluster. Although hundreds of transiting multi-planet systems have been discovered so far (see, e.g., Rowe et al. 2014), this system is of particular interest because of its relatively well-known age and proximity to the Sun, which enhance the prospects for further characterization. Because the

<sup>23</sup> JSPS Fellow.

star hosts multiple transiting planets, the architecture of a young planet system can be explored by measuring the densities, compositions, and orbital parameters of the planets. Furthermore, because the Sun is believed to have formed in a cluster (e.g., Adams 2010), studying planets in clusters can potentially shed light on how our own solar system formed.

The transit detections and follow-up observations that led to this discovery were the result of an international collaboration called KESPRINT. While this manuscript was in preparation, we learned that this same system had been independently discovered by Ciardi et al. (2018) and Mann et al. (2018). It is not surprising that multiple groups chose this unique system for a large investment in telescope resources.

This paper is organized as follows. We describe the data in Section 2, transit analysis in Section 3, and stellar parameters in Section 4. We validate the system in Section 5, discuss the potential for future study (and other interesting aspects) of the system in Section 6. In the final section, we summarize our results and compare them to the two other studies reporting the discovery of this remarkable system.

## 2. Observations

### 2.1. K2 Photometry

The high-proper-motion star LP 358-348 (EPIC 247589423) was proposed as a K2 Campaign 13 (C13) target by numerous programs: GO13008 (PI Mann), GO13049 (Quintana), GO13064 (Agueros), GO13018 (Crossfield), GO13023 (Rebull), GO13077 (Endl), and GO13090 (Glaser). The star was monitored in long-cadence mode with detector module 19 of the *Kepler* photometer from 2017 March 8 to May 27 UT. Table 1 gives the star's basic parameters.

Because of the loss of two of its four reaction wheels, the *Kepler* spacecraft is susceptible to uncontrolled rotation around the axis of its boresight. This causes stars to appear to vary in intensity, due to their motion across the detector coupled with gain variations within and between pixels. Some of these spurious variations can be removed through straightforward decorrelation, as first reported by Vanderburg & Johnson (2014). We downloaded the target pixel files from the *Mikulski Archive for Space Telescopes*.<sup>24</sup> For each star, we defined an aperture around the brightest pixel and fitted the intensity distribution with a two-dimensional (2D) Gaussian function. We then fitted a piecewise linear function between the time series of aperture flux and the central coordinates of the light distribution. We used the best-fitting function to decorrelate the light curve from the positional variations. We experimented with different apertures to minimize the 6 hr Combined Differential Photometric Precision of the resulting light curve. Figure 1 illustrates the optimal aperture, Figure 2 shows the corresponding light curve, and the phase-folded transits are shown in Figure 3.

### 2.2. NOT/FIES High-resolution Spectroscopy

As part of the CAT observing program P55-206, on 2017 September 14 UT we acquired a high-resolution spectrum of K2-136 with the Fibre-fed Échelle Spectrograph (FIES; Frandsen & Lindberg 1999; Telting et al. 2014) attached to the 2.56 m Nordic Optical Telescope (NOT) of Roque de los Muchachos Observatory (La Palma, Spain). The observation was carried out

**Note.** Hub2016 and Wei83 refer to Huber et al. (2016) and Weis (1983), respectively. Values marked with UCAC2, TASS, 2MASS, and WISE are from Zacharias et al. (2004), Droege et al. (2006), Cutri et al. (2003), Cutri et al. (2013), respectively. The WISE W4 magnitude is an upper limit.

**Figure 1.** The photometric aperture (red silhouette) used to create the K2 light curve. The green circle indicates the position of the target in the EPIC catalog. The blue circle is the center of the flux distribution.

<sup>24</sup> <https://archive.stsci.edu/k2/>

**Figure 2.** Light curves of K2-136 produced by our pipeline. The upper panel shows the systematics-corrected light curve, in which transits of all three planets can be identified by eye. The lower panel shows the same light curve after removing the stellar variability signal, with the best-fitting transit model for each planet in the system plotted in a different color: planet b—red; planet c—green; planet d—blue.

**Figure 3.** Phase-folded transits of each planet in the system, in order of increasing orbital period (left to right). The best-fitting transit model for each planet is plotted using the same colors as in Figure 2.

using the instrument’s *high-res* mode, which provides a resolving power of  $R = 67,000$  in the spectral range 3700–8300 Å. The exposure time was set to 1800 s, leading to a signal-to-noise ratio (S/N) of about 35 per pixel at 5500 Å. Following the same observing strategy our team has adopted for other FIES observations of K2 stars (see, e.g., Gandolfi et al. 2017), we traced the RV drift of the instrument with long-exposed (100 s) ThAr spectra bracketing the science exposure. The data reduction was performed using standard IRAF routines (Tody 1986). The RV measurement was extracted by cross-correlating the observed échelle spectrum with a template of the K5 V RV standard star HD 190007 (Udry et al. 1999). We found that K2-136 has an absolute RV of  $39.2 \pm 0.1 \text{ km s}^{-1}$  (Table 1), which is consistent with membership in the Hyades cluster. We note that the quoted uncertainty takes into account the uncertainty of the absolute RV of the standard star. We also found no evidence of additional peaks in the cross-correlation function that might be produced by additional stars in the system.

### 2.3. Seeing-limited Imaging

We obtained seeing-limited images of the target field in the  $z_s$  band on 2017 September 24 UT, using the Multicolor Simultaneous Camera for studying Atmospheres of Transiting exoplanets (MuSCAT; Narita et al. 2015) mounted on the

188 cm telescope at Okayama Astrophysical Observatory (OAO). The field of view of MuSCAT is  $6'.1 \times 6'.1$ . The sky was photometric with an average seeing of  $1''.0$ . A set of 20 images was obtained with individual exposure times of 3 s. The images were median-combined after performing corrections for dark current, flat-fielding, and field distortion. The left panel of Figure 4 shows the combined image. The coordinates of the reduced image were then calibrated to the equatorial coordinate system (J2000) via the *Gaia* DR1 catalog (Gaia Collaboration et al. 2016) with an accuracy of  $0''.04$  in rms, from which we measured the target coordinate at epoch = 2017.73 to be  $(\alpha, \delta)_{\text{J2000}} = (04:29:38.990, +22:52:57.80)$ .

### 2.4. Lucky Imaging

We performed Lucky Imaging (LI) of K2-136 using FastCam (Oscoz et al. 2008) at the NOT in the Observatorio Roque de los Muchachos, La Palma. This instrument is an optical imager with a low-noise EMCCD camera capable of obtaining speckle-featuring non-saturated images at a fast frame rate (see Labadie et al. 2011). On 2017 October 5th UT, we obtained 20000 images in the *I* band with an exposure time of 30 msec per image.

In order to construct a high-resolution, diffraction-limited, long-exposure image, the individual frames were bias

**Figure 4.** The seeing-limited  $z$  band image of K2-136 obtained by MuSCAT in 2017 (left) and the POSS1 Red image of the same field obtained in 1950 (right). North is up and east is to the left. The gray lines indicate the location of the target measured on the MuSCAT image.

subtracted, aligned and co-added using our own LI algorithm (see Velasco et al. 2016). The LI selection is based on the brightest speckle in each frame, which has the highest concentration of energy and represents a diffraction-limited image of the source. Those frames with the largest count number at the brightest speckle are the best ones. The percentage of the best frames chosen depends on the natural seeing conditions and the telescope diameter. It is based on a trade between a sufficiently high integration time, given by a higher percentage, and a good angular resolution, obtained by co-adding a lower amount of frames. Figure 5 presents the high-resolution image constructed by co-addition of the best 10% of all frames, i.e., with a total exposure time of 60 s. The image was processed with  $5 \times 5$  pixel Gaussian kernel filtering followed by  $3 \times 3$  pixel Gaussian smoothing to reduce pixel noise (Labadie et al. 2011). The figure also shows the contrast curve that was computed based on the scatter within the annulus as a function of angular separation from the target centroid. No bright companion was detectable in the images within  $1''$ .

Ciardi et al. (2018) reported the detection of a secondary M7/8V star  $\sim 0.7''$  to the south of the primary star based on their analysis of adaptive optics imaging obtained with Keck/NIRC2 and Palomar/PHARO. To assess the sensitivity of our  $I$  band FastCam image to this companion, we computed the detection limit of FastCam along the axis to the south of the primary star. We measured a detection limit of  $3.33 \pm 1.8 [\Delta\text{mag}]$  at the approximate location of the companion. The primary star has an  $I$  band magnitude of  $10.072 \pm 0.118$ , so our detection limit corresponds to  $I \approx 13.4$ . According to Table 5 of Pecaut & Mamajek (2013), an M7/8V star has colors of  $V-I \approx 4.5$  and  $V-K_S \approx 8$ , meaning  $I-K_S \approx 3.5$ . Ciardi et al. (2018) estimate  $K_S \approx 13$  for the companion, which implies  $I \approx 16.5$ ; thus, the companion is well below the detection limit of  $\sim 13.4$  in our FastCam image.

### 3. Transit Analysis

Before searching the light curve for transits, we reduced the amplitude of any long-term systematic or instrumental flux variations by fitting a cubic spline to the light curve. To look for periodic transit signals, we employed the Box-Least-Squares algorithm (BLS; Kovács et al. 2002). We improved the

**Figure 5.** The  $I$  band image of K2-136 (inset,  $3.1'' \times 3.1''$ ) from NOT/FastCam and resulting  $5\text{-}\sigma$  contrast curve. North is up and east is to the left.

efficiency of the original BLS algorithm by using a nonlinear frequency grid that takes into account the scaling of transit duration with orbital period (Ofir 2014). We also adopted the signal detection efficiency (SDE; Ofir 2014) which quantifies the significance of a detection. The SDE is defined by the amplitude of peak in the BLS spectrum normalized by the local standard deviation. We set a threshold of  $\text{SDE} > 6.5$  as a good balance between completeness and false-alarm rate. In order to identify all of the transiting planets in the same system, we progressively re-ran BLS after removing the transit signal detected in the previous iteration. The lower panel of Figure 2 shows the resulting light curve and transits identified by this analysis, and Figure 3 shows the phase-folded transit for each planet.

We used the orbital period, mid-transit time, transit depth, and transit duration identified by BLS as the starting points for more detailed transit modeling. To reduce the data volume, we only analyzed the data obtained within  $2 \times T_{14}$  window of mid-transits, where  $T_{14}$  is the transit duration. First, we tested if any of the planets exhibited transit-timing variations (TTVs). We fitted the phase-folded transit light curve to a model generated by the Python package batman (Kreidberg 2015). Then we used the best-fitting model as a template for the

**Table 2**  
Fitted and Derived Transit Parameters

Parameter			
$\rho_*$ (g cm $^{-3}$ )	$3.25^{+0.61}_{-0.73}$

$R_p/R_*$	$0.01337^{+0.00064}_{-0.00070}$	$0.03981^{+0.00065}_{-0.00066}$	$0.0197^{+0.0010}_{-0.0007}$
$T_c$ (BJD-2454833)	$2992.7295^{+0.0067}_{-0.0063}$	$2997.02487^{+0.00077}_{-0.00073}$	$2998.9610^{+0.0040}_{-0.0041}$
$a/R_*$	$22.2^{+1.3}_{-1.8}$	$39.4^{+2.2}_{-3.0}$	$48.3^{+2.8}_{-3.9}$
Inclination (°)	$89.2 \pm 0.6$	$89.7^{+0.2}_{-0.3}$	$89.4^{+0.4}_{-0.3}$
$b$	$0.32^{+0.25}_{-0.23}$	$0.20^{+0.22}_{-0.14}$	$0.49^{+0.34}_{-0.33}$
$e$	<0.72 (95% conf. level)	<0.47 (95% conf. level)	<0.75 (95% conf. level)
$R_p$ ( $R_{\oplus}$ )	$1.05 \pm 0.16$	$3.14 \pm 0.36$	$1.55^{+0.24}_{-0.21}$

determination of individual transit times. Holding all parameters fixed except the mid-transit time, we fitted the template to the data surrounding each transit. We did not detect any TTVs over the  $\approx 80$  days of *K2* observations. For subsequent analysis, we assumed that all three transit sequences were strictly periodic.

The parameters in our light-curve model include three parameters that pertain to all the transits: the mean density of the host star,  $\rho_*$ ; and the quadratic limb-darkening coefficients,  $u_1$  and  $u_2$ . Each planet is parameterized by its orbital period,  $P_{\text{orb}}$ ; the time of a particular transit,  $t_c$ ; the planet-to-star radius ratio,  $R_p/R_*$ ; the impact parameter,  $b \equiv a \cos i/R_*$ ; and the eccentricity parameters  $\sqrt{e} \cos \omega$  and  $\sqrt{e} \sin \omega$ . We imposed Gaussian priors on the limb-darkening coefficients based on the values from EXOFAST<sup>25</sup> (Eastman et al. 2013), with Gaussian widths of 0.2. We imposed Jeffreys priors on the scale parameters  $P_{\text{orb}}$ ,  $R_p/R_*$ , and  $\rho_*$ . We imposed uniform priors on  $t_c$ ,  $\cos i$ ,  $\sqrt{e} \cos \omega$ , and  $\sqrt{e} \sin \omega$ . We computed the model light curve at 1-minute intervals and then averaged into 30-minute intervals before comparing with the data (Kipping 2010).

We adopted the usual  $\chi^2$  likelihood function. We found the maximum likelihood solution using the Levenberg–Marquardt algorithm implemented in the Python package *lmfit* (Newville et al. 2014). We sampled the posterior distribution of transit parameters by performing a Markov Chain Monte Carlo analysis with *emcee* (Foreman-Mackey et al. 2013). We launched 128 walkers in the vicinity of the maximum likelihood solution. We ran the walkers for 5000 links and discarded the first 1000 as the burn-in phase. We checked for convergence by calculating the Gelman–Rubin potential scale reduction factor. Adequate convergence was achieved since the Gelman–Rubin factor dropped to within 1.03 and the resultant posterior distributions for various parameters were smooth and unimodal. Table 2 reports the transit parameters using the 16%, 50%, and 84% levels of the posterior distribution.

Near BJD–2454833 = 3024.5, the transits of planet b and d partially overlapped with each other, resulting in a double transit (see Figure 6). Given the precision and 30-minute averaging of the *K2* light curve, we cannot tell if the planets

**Figure 6.** Overlapping transits of planets b and d, which occurred just before the halfway point of the full time series plotted in Figure 2.

exhibited a mutual eclipse, which would have revealed the mutual inclination between their orbits (Hirano et al. 2012). According to our constant-period ephemeris, the next double transit will occur at BJD–2454833 = 3893.9836 (UT 2019 August 31 11:36).

#### 4. Stellar Parameters

We analyzed the combined FIES spectrum to derive the spectroscopic parameters of K2-136. We extracted the spectral region between 5000 and 6000 Å and fed it to the *SpecMatch-emp* code developed by Yee et al. (2017). *SpecMatch-emp* refers to the library of high-resolution spectra for hundreds of FGKM stars and tries to find a subset of spectra that best match the input spectrum. The final set of parameters ( $T_{\text{eff}}$ ,  $R_*$ , and [Fe/H]) is estimated by interpolation between the stellar parameters of the best-matched spectra. We converted the spectroscopically derived  $T_{\text{eff}}$ ,  $R_*$ , and [Fe/H] into mass  $M_*$ , surface gravity  $\log g$ , mean density  $\rho_*$ , and luminosity  $L_*$  using the empirical relations derived by Torres et al. (2010). Assuming that  $T_{\text{eff}}$ ,  $R_*$ , and [Fe/H] have uncertainties well described by Gaussian functions, with means and standard deviations as determined by *SpecMatch-emp*, we performed Monte Carlo simulations to derive  $M_*$ ,  $\log g$ ,  $\rho_*$ , and  $L_*$ . We also measured the projected rotational velocity of the star ( $v \sin i_*$ ) by fitting the profiles of unblended and isolated metal lines using the ATLAS12 model spectrum (Kurucz 2013) with the same spectroscopic parameters as the star. We find  $T_{\text{eff}} = 4359 \pm 70$  K, [Fe/H] =  $0.17 \pm 0.12$  dex,  $\log g = 4.537 \pm 0.086$  cgs,  $M_* = 0.686 \pm 0.028 M_{\odot}$ ,  $R_* = 0.723 \pm 0.072 R_{\odot}$ ,  $\rho_* = 1.92 \pm 0.54 \rho_{\odot}$ , and  $L_* = 0.171 \pm 0.036 L_{\odot}$  (see Table 1). We also computed the mean stellar density from the measured transit parameters for each planet, assuming a circular orbit, and found  $2.35 \pm 0.57$ ,  $2.79 \pm 0.63$ , and  $2.36 \pm 0.56 \rho_{\odot}$  for planets b, c, and d, respectively, which are all consistent with the spectroscopically derived value at the  $1\sigma$  level.

We determined the interstellar extinction and spectroscopic distance to K2-136 following the procedure described by Gandolfi et al. (2008). Briefly, we created synthetic intrinsic colors from the NEXTGEN model spectrum (Hauschildt et al. 1999) with the same spectroscopic parameters as the star. We then simultaneously fitted the synthetic colors to the observed colors (Table 1) encompassed by the spectral energy distribution of the star (Figure 7). Assuming the conventional extinction law,  $R_v = A_v/E(B-V) = 3.1$ , we found a

<sup>25</sup> <http://astroutils.astronomy.ohio-state.edu/exofast/limbdark.shtml>

**Figure 7.** Dereddened spectral energy distribution of K2-136. The NEXTGEN model spectrum with the same parameters as the star is plotted with a light blue line. The *B*, *V*, *I*, *J*, *H*, *Ks*, *W1*, *W2*, *W3*, and *W4* fluxes are derived from the magnitudes reported in Table 1. The *WISE* *W4* magnitude is an upper limit.

reddening of  $A_V = 0.1 \pm 0.1$  mag. Based on this value of reddening, the observed fluxes, and the approximation of a blackbody spectrum, we derived a spectroscopic/photometric distance of  $d = 63.5 \pm 7.0$  pc. Röser et al. (2011) reported a secular parallax of  $17.21 \pm 0.30$  mas for the star, corresponding to a distance of  $58.1 \pm 1.0$  pc, which is in good agreement with the distance we report here.

We derived independent estimates of the stellar mass, radius, and age using the web interface to the PARSEC 1.3 isochrones.<sup>26</sup> We combined the stellar parameters we report in this work ( $T_{\text{eff}}$ ,  $[\text{Fe}/\text{H}]$ ,  $V$  mag,  $A_V$ ) with the distance of  $58.1 \pm 1.0$  pc from the secular parallax reported by Röser et al. (2011) and obtained  $M_* = 0.696 \pm 0.017 M_\odot$ ,  $R_* = 0.634 \pm 0.014 R_\odot$ ,  $\log g = 4.648 \pm 0.016$  cgs, and age =  $4.675 \pm 4.020$  Gyr. This agrees very well with our result in stellar mass ( $M_* = 0.686 \pm 0.028 M_\odot$ ) and moderately well (within  $1.5\sigma$ ) in stellar radius ( $R_* = 0.723 \pm 0.072 R_\odot$ ). The disagreement with the prediction from the PARSEC 1.3 isochrones likely reflects the fact that stellar evolution models do not account for magnetic activity, which is believed to be the source of inflation in late type stars (e.g., Torres 2013); thus, the stellar radius is likely to be underestimated by these models. We note that the radii of most of the template stars used by SpecMatch-emp have been accurately measured via interferometry, asteroseismology, and spectrophotometry and do not rely on stellar evolution models.

We also computed a 600 Myr PARSEC isochrone for  $Z = 0.02586$ , i.e., the metal content of K2-136. We found that a star of  $M_* = 0.686 M_\odot$  has a luminosity of  $L_* = 0.1059 L_\odot$  (we report  $L_* = 0.171 \pm 0.036 L_\odot$ ),  $T_{\text{eff}} = 4113$  K (we report  $T_{\text{eff}} = 4359 \pm 70$  K),  $\log g = 4.657$  cgs (we report  $\log g = 4.537 \pm 0.086$  cgs). This implies  $R_* = 0.643 R_\odot$ , whereas we report  $R_* = 0.723 \pm 0.072 R_\odot$ , which once again is consistent with a moderate underestimate of the stellar radius in the PARSEC isochrones.

The *K2* light curve shows quasi-periodic variability that is likely caused by rotation (see the upper panel of Figure 2). To determine the rotation period, we used a variety of methods: the autocorrelation function (ACF; e.g., McQuillan et al. 2014), the Lomb–Scargle periodogram (Lomb 1976; Scargle 1982), and Gaussian Process (GP) regression (Rasmussen & Williams

2005). For the GP regression, we used the *celerite* package (Foreman-Mackey et al. 2017) with a quasi-periodic covariance function (e.g., Haywood et al. 2014; Grunblatt et al. 2015; Angus et al. 2017). The GP, Lomb–Scargle, and ACF methods yield a stellar rotation period of  $13.5^{+0.7}_{-0.4}$ ,  $15.1^{+1.3}_{-1.2}$ , and  $13.6^{+2.2}_{-1.5}$  days, respectively. All three of these methods produce results that are consistent at the  $1\sigma$  level, with the best agreement between the results from GP regression and the ACF. See Figures 8 and 9 for visualizations of these methods. We adopt the ACF value for the stellar rotation value in Table 1, as it is in good agreement but the error bars are more conservative. The FIES spectrum reveals emission components in the cores of the Ca II H & K lines (see Figure 10), as expected given the photometric variability observed in the *K2* light curve (see Figure 8). Unfortunately, the S/N is too low to provide a meaningful measurement of the Ca activity indicator. Using the rotation period of the star and the empirical equation given by Suárez Mascareño et al. (2015) we estimated that  $\log_{10}(R'_{\text{HK}})$  is expected to be between  $-4.7$  and  $-4.5$ .

We estimated the level of spurious RV variations that should be produced by stellar activity using the code SOAP2 (Dumusque et al. 2014). Adopting a plausible range of values for the spot temperature (Strassmeier 2009), and using the stellar radius, rotation period, effective temperature, and limb-darkening coefficients given in Tables 1 and 2, we found that the observed peak-to-peak photometric variability of  $\sim 0.5\%$ – $0.9\%$  (Figure 2) implies a RV jitter with a semi-amplitude of  $\sim 5$ – $10 \text{ m s}^{-1}$ . This will interfere with efforts to measure the planet masses by RV monitoring.

## 5. Validation

Before prioritizing newly detected planet candidates for detailed follow-up characterization, it is useful to consider the false positive probability (FPP), i.e., the probability that the observed signal is actually caused by an eclipsing binary (EB). High-resolution imaging is important to search for faint nearby objects which could be the source of the signal or could be reducing its apparent amplitude. Our imaging data revealed no such faint companions (see the left panel of Figures 4 and 5). In addition, the proper motion of the host star combined with the POSS I image from 1950 shows no obvious background source which would be aligned with the host star today (see right panel of Figure 4). These results place stringent limits on the separation between the host star and any putative bound stellar companions, and effectively rule out a present-day alignment with a background EB.

Stars with multiple transiting planet candidates are known to have a very low false positive rate (Lissauer et al. 2011, 2012, 2014). Furthermore, the orbital periods of this system are nearly in the ratio 3:2:1, which is a priori difficult to reproduce with a combination of multiple non-planetary eclipsing systems. We therefore expect the FPP for this system to be exceedingly low. We tried to quantify the FPP using the statistical validation framework as implemented in the *vespa* code (Morton 2012, 2015). This code uses the TRILEGAL Galaxy model (Girardi et al. 2005) to compute the likelihoods of both planetary and non-planetary scenarios given the observed transit signals, and considers EBs, background EBs, and hierarchical triple systems (HEBs). After applying the empirical “multiplicity boost” from Lissauer et al. (2012), the FPPs from *vespa* are well below the fiducial validation

<sup>26</sup> Available at [http://stev.oapd.inaf.it/cgi-bin/param\\_1.3](http://stev.oapd.inaf.it/cgi-bin/param_1.3).

**Figure 8.** Measurement of the stellar rotation period via star spot modulation. The left plot shows the data with transits removed (black points) and a Gaussian Process regression with a quasi-periodic kernel (green line and 1- $\sigma$  credible region). The right plot shows the light curve folded on the maximum a posteriori period, in which data points closer in time have more similar colors. Sampling the GP model posterior yields a rotation period of  $13.5^{+0.7}_{-0.4}$  days.

criterion of  $\sim 1\%$  for all planets in this system. We conclude that K2-136 is a *bona fide* three-planet system.

## 6. Discussion

Using the results of our spectroscopic and transit light curve analysis, we determine the radii of planets b, c, and d to be  $1.05 \pm 0.16$ ,  $3.14 \pm 0.36$ , and  $1.55^{+0.24}_{-0.21} R_{\oplus}$ , respectively. Using the empirical mass–radius relation of Wolfgang et al. (2016), the masses are expected to be  $1.5^{+1.7}_{-1.0}$ ,  $11.6^{+3.1}_{-3.0}$ , and  $4.6^{+2.4}_{-2.3} M_{\oplus}$ , respectively.

Combining our transit and spectroscopic analyses yields a semimajor axis of 0.1624 au and an insolation flux of about  $6.5 S_{\oplus}$  for planet d, which is well inside the inner edge of the “recent Venus” habitable zone for this star (Kopparapu et al. 2013). Its size of  $1.55 R_{\oplus}$  and equilibrium temperature of 430 K (assuming a Bond albedo of 0.3) make this an interesting target for studying the atmospheres and compositions of small temperate planets near the rocky-gaseous transition.

There are only a small number of known planetary systems with a similar architecture close to a 3:2:1 mean-motion resonance. K2-32 (Dai et al. 2016; Sinukoff et al. 2016; Petigura et al. 2017) hosts three planets which have period ratios near 3:2:1 but not as close as the period ratios of K2-136. In addition, the planets in the K2-32 system are substantially larger than the planets orbiting K2-136. The Kepler-19 system is also close to this resonance, but only one of the planets transits the host star—the other two were detected via TTV and RV measurements (Ballard et al. 2011; Malavolta et al. 2017). Kepler-51 is a system of three Saturn-size planets with masses measured from TTVs (Steffen et al. 2013; Masuda 2014). Rowe et al. (2014) announced the validation of several systems which are within  $\sim 10\%$  of this resonance: Kepler-184, Kepler-254, Kepler-326, and Kepler-363. K2-136 stands out from all of these other systems due to its brighter host star, cluster membership, and the small size of its planets—in particular planet b, which is smaller than all of the planets in these systems. In addition, K2-136 is the only system among these in which the middle planet is substantially larger than both of its neighbors.

### 6.1. Potential for Future Study

The planets in this system are attractive targets for follow-up RV and transmission spectroscopy studies, due to the relative

brightness of the host star ( $J = 9.1$ ). The star exhibits relatively low-amplitude photometric spot modulation ( $\sim 0.3\%$  on average), a moderate  $v \sin i_{\star}$  of  $2.6 \pm 0.7 \text{ km s}^{-1}$ , and relatively low levels of activity for its age, which enhance the prospects for precise mass measurement via RV monitoring. Nevertheless, it will still not be easy. Given the masses from mass–radius relations, the predicted RV semi-amplitudes of planets b, c, and d are  $\sim 0.5$ ,  $\sim 4$ , and  $\sim 1 \text{ m s}^{-1}$ . Such small signals are detectable in principle with current and planned spectrographs. We note, however that the level of spurious Doppler shifts produced by stellar activity is expected to be  $5\text{--}10 \text{ m s}^{-1}$  (see Section 4) and the rotation period of the star lies between the orbital periods of planets b and c. It will require great care to disentangle the planetary signals from those induced by stellar activity.

It is worth noting that our estimate of the projected rotational velocity ( $v \sin i_{\star} = 2.6 \pm 0.7 \text{ km s}^{-1}$ ) agrees with the equatorial rotation velocity ( $v_{\text{eq}} = 2.69^{+0.40}_{-0.51} \text{ km s}^{-1}$ ) estimated from the stellar radius and rotation period. This is consistent with  $\sin i = 1$ , which is a necessary (but not sufficient) condition for spin–orbit alignment. The stellar inclination, an indicator of stellar obliquity for transiting systems, has been discussed in the literature (see, e.g., Hirano et al. 2014; Morton & Winn 2014) as a probe to investigate the dynamical history of planetary systems, but essentially nothing is known about the obliquity for planetary systems in stellar clusters.

The 30-minute averaging of K2 data limits our ability to detect TTV signals smaller in amplitude than about 30 minutes. Nevertheless, there is a tantalizing hint of possible dynamical interactions between planets c and d (see Figure 11). The apparent anti-correlation between the TTVs of each planet is similar to what one would expect given the proximity to a period commensurability ( $P_d/P_c \approx 1.48$ ). Using the analytic formulae of Lithwick et al. (2012), the expected super-period for this pair is  $\sim 570$  days. Neither the timing precision nor the time baseline of the existing data is sufficient to constrain any possible TTVs. There do not appear to be significant dynamical interactions between planets b and c, which is not surprising because their orbital periods are further from commensurability ( $P_c/P_b \approx 2.17$ ). Future photometric monitoring of this system, perhaps with the upcoming CHEOPS space telescope (Broeg et al. 2013), may reveal dynamical interactions in this system. This would make precision RV monitoring of this system even more interesting, as the RV measurements could help break the

**Figure 9.** Measurement of the stellar rotation period using the ACF (left) and the Lomb–Scargle periodogram (right). The vertical solid and dashed lines in each plot indicate the peak signal and its FWHM. Autocorrelation yields  $13.6^{+2.2}_{-1.5}$  days. The Lomb–Scargle periodogram yields  $15.1^{+1.3}_{-1.2}$  days. Both are consistent with each other and the GP model at the  $1\sigma$  level.

usual degeneracy between mass and eccentricity in TTV analysis.

### 6.2. Cluster Membership

We computed the cluster membership probability of K2-136 based on the combined probability from proper motion and RV. We used the UCAC5 (Zacharias et al. 2017) proper motion and the absolute RV we measured with FIES (see Table 1). The proper motion probability was measured following the method described in Vasilevskis et al. (1958) and assuming that the average proper motion of the Hyades is  $\mu_\alpha = 104.92 \pm 0.12$  and  $\mu_\delta = -28.0 \pm 0.09$  mas yr<sup>-1</sup> (Gaia Collaboration et al. 2017). The computation of the multivariate probability density functions was performed with the `scipy.stats` Python package (Jones et al. 2001). The RV-based membership probability was determined by comparing the RV of the star to the average RV of the cluster members, assuming that the velocity distribution of the Hyades cluster can be approximated by a single Gaussian with an absolute velocity of  $RV_{Hy} = 39.29$  km s<sup>-1</sup> and  $\sigma_{Hy} = 0.25$  km s<sup>-1</sup> (Dias et al. 2002). The final combined membership probability is  $P_c = P_\mu \times P_{RV} = 0.94$ , which is in very good agreement with the value of 0.92 found by Douglas et al. (2014).

We determined the gyrochronological age of the star using rotation–activity–age relations. From  $(B - V) = 1.300 \pm 0.015$  mag (Weis 1983), we obtained  $t_{gyro} = 284 \pm 248$  Myr using the relation of Barnes (2007),  $t_{gyro} = 558 \pm 329$  Myr using Mamajek & Hillenbrand (2008), and  $t_{gyro} = 667 \pm 504$  Myr using Angus et al. (2015). This range of gyrochronological ages is consistent with a moderately young star, lending further support to the host star’s cluster membership.

Röser et al. (2011) determined K2-136 to be a Hyades member and reported a secular parallax of  $17.21 \pm 0.30$  mas, corresponding to  $58.1 \pm 1.0$  pc, which is consistent with our distance estimate of  $63.5 \pm 7.0$  pc. The proper motion of the star is consistent with that of well-known, bright cluster members such as 71 Tau, ups Tau, c Tau, and Prima Hyadum. Our measurement of the star’s absolute  $RV = 39.2 \pm 0.1$  km s<sup>-1</sup> is also consistent with that of the average Hyades member star ( $39.1 \pm 0.2$  km s<sup>-1</sup>, Detweiler et al. 1984).

We conclude that K2-136 is a *bona fide* Hyades member. Thus, its age is likely in the range 600–800 Myr (Perryman et al. 1998; Brandt & Huang 2015), making its planets among the smallest known with well-determined ages. We note that the age of  $\sim 800$  Myr determined by Brandt & Huang (2015) is

the result of a revised metallicity and accounting for the effects of stellar rotation, so we include it in the range of plausible ages listed here along with the previous consensus estimate. The best estimate of the age of these planets is therefore likely to have significantly lower uncertainty than that implied by the full range.

### 6.3. System Architecture

Due to its small size, planet b is likely to be rocky in composition, whereas the larger planet c is likely to have a substantial gaseous envelope. These planets could therefore be sitting on either side of the theorized “photoevaporation valley” (e.g., Owen & Wu 2013; Lopez & Fortney 2014) for which strong observational evidence has recently emerged (Fulton et al. 2017; Van Eylen et al. 2017). Because of the well-known age of Hyades members, the planets in this system could therefore provide a laboratory to test theories of atmospheric loss from incident stellar irradiation, as they share a common history of host star activity. Planet b receives  $\sim 30$  times the insolation flux of Earth, so given its current radius it may have had a substantial primordial atmosphere, which was subsequently lost due to photoevaporation. In such a scenario, planet c receives lower levels of incident flux from the host star and could have a sufficiently massive core for it to retain its atmosphere. The situation is less clear for planet d, which could either have formed without a substantial atmosphere and remained close to its primordial size or perhaps also experienced photoevaporation. Testing such a hypothetical scenario via future Doppler mass measurements will provide insights into planetary atmospheric evolution.

## 7. Summary

We have presented our analysis of the K2 light curve of the star K2-136, along with the results of our ground-based imaging and spectroscopy follow-up observations. The star hosts three small transiting planets with orbital periods in close proximity to a 3:2:1 resonant chain, including one planet approximately the size of Earth, one super-Earth, and one sub-Neptune. The host star’s membership in the Hyades makes this the first transiting multi-planetary system currently known in a cluster and yields a precise age for the system, making the innermost planet the smallest and youngest discovered around any star to date. The system presents excellent prospects for future characterization via RV and transmission spectroscopy observations, which will enable tests of planet formation and migration theories.

**Figure 10.** Cores of the Ca II H & K lines as observed with FIES.

**Figure 11.** The individual transit times of the three planets. Transits that were severely affected by systematics were removed.

While this manuscript was in preparation, Ciardi et al. (2018) and Mann et al. (2018) reported independent analyses of this system, each utilizing their own *K2* photometric pipelines. Because each pipeline has potentially significant differences in the way *K2* systematics are modeled, it is worthwhile to check for consistency among the reported values (e.g., Dressing et al. 2017). For example, the transit depth could be artificially reduced by an overly aggressive systematics model, or a single photometric measurement contaminated by an undetected cosmic ray could result in a biased ephemeris (e.g., *K2*-18b; Benneke et al. 2017). We compared our results for  $R_p/R_*$  and

$P_{\text{orb}}$  to those reported by the other two teams and found them to be consistent to within  $1\sigma$ , indicating a relatively high level of reliability. We also compared our stellar parameters ( $T_{\text{eff}}$ ,  $\log g$ ,  $[\text{Fe}/\text{H}]$ , and  $R_*$ ) to those reported by these other two teams. We found that our values and those reported by Ciardi et al. (2018) agree to within  $\sim 0.5\sigma$ , but there is mild disagreement ( $\sim 1.5\sigma$ ) with those reported by Mann et al. (2018) for  $T_{\text{eff}}$  and  $\log g$ . This could be due to differences in the modeling approaches taken or to overly optimistic uncertainties, or a combination of both. We also found moderate disagreement between the reported barycentric RV values, but this is likely due to a systematic shift of the RV zero points. However, the agreement in  $R_*$  from all three teams is better than  $1\sigma$ , yielding a robust set of planetary radii. Furthermore, the orbital ephemerides we report are similarly robust, which is essential for efficient scheduling of future transit observations (i.e., with *Spitzer* or *JWST*).

This work is based on observations obtained with the NOT, operated on the island of La Palma jointly by Denmark, Finland, Iceland, Norway, and Sweden, in the Spanish Observatorio del Roque de los Muchachos (ORM) of the Instituto de Astrofísica de Canarias (IAC). We are very grateful to the NOT staff members for their unique and superb support during the observations. J.H.L. gratefully acknowledges the support of the Japan Society for the Promotion of Science (JSPS) Research Fellowship for Young Scientists. D.G. gratefully acknowledges the financial support of the *Programma Giovani Ricercatori—Rita Levi Montalcini—Rientro dei Cervelli* (2012) awarded by the Italian Ministry of Education, Universities and Research (MIUR). This research has made use of the NASA Exoplanet Archive, which is operated by the California Institute of Technology, under contract with the National Aeronautics and Space Administration under the Exoplanet Exploration Program. This work was supported by JSPS KAKENHI grant No. JP16K17660. H.J.D. and D.N. acknowledge support by grant ESP2015-65712-C5-4-R of the Spanish Secretary of State for R&D&i (MINECO). This paper includes data collected by the *Kepler* mission. Funding for the *Kepler* mission is provided by the NASA Science Mission directorate.

*Facilities:* *Kepler*, NOT (FIES, FastCam), OAO:1.88 m (MuSCAT).

*Software:* scipy, emcee, batman, celerite, vespa, IRAF.
