Design Trade-offs in Feed Systems for Ultra-wideband VLBI Observations

Jonas Flygare, Miroslav Pantaleev, John Conway, Michael Lindqvist, Rüdiger Haas

Abstract Due to the advanced capability of today’s ultra-wideband feed systems and low-noise amplifiers, interesting upgrades for future VLBI receiver and telescope design should be considered. Multiple input parameters need to be taken into account for optimal sensitivity and applications of the future astronomical and geodetic observational systems. In this paper we present an overview of some trade-offs for wideband systems between SEFD, bandwidth, and telescope reflector optics. We evaluate receiver bandwidths from 3.5:1 to 10.3:1 bandwidth within the frequency range 1.5–24 GHz in different configurations. Due to potential RFI pollution of the lower frequencies we present potential feed upgrades for the most common reflector geometries of VGOS and EVN telescopes that mitigate this problem. The results of this work is relevant for future VLBI stations and telescope design in general.

Keywords SEFD, VLBI, ultra wideband, VGOS, Quad-Ridge Flared Horn

1 Introduction

The VLBI Global Observing System (VGOS) network typically uses frequencies over 2–18 GHz with receiver bandwidth ratios of 6:1. The benefit of wideband feed systems is that continuous observational bandwidth will be available, at the expense of absolute system equivalent flux density (SEFD) over frequency. Despite this trade-off, with current state-of-the-art low-noise amplifiers (LNA) and highly optimized feed antennas, a good sensitivity (SEFD) level can still be achieved.

The research project BRoad-bAND (BRAND), funded by EU Horizon 2020 RadioNet, will cover a decade in frequency over 1.5–15.5 GHz with a single-pixel feed [1]. This receiver system will enable continuous observations within the European VLBI Network (EVN) over L-, S-, C-, X-, and Ku-band. We evaluate the BRAND feed with simulations in a VGOS reflector, the Onsala Twin Telescope (OTT) [2], see Figure 1, and compare to the current system installed on one of the telescopes [3]. Due to the radio frequency interference (RFI) pollution at L- and S-band frequencies and the probable release of more frequencies for 5G telecommunication, potential new frequency bands should also be investigated. With respect to this, we present the high-frequency quad-ridge flared horn (QRFH) developed for the Square Kilometre Array (SKA) project covering 4.6–24 GHz [4] and evaluate it in the VGOS reflector through simulations. These feeds are optimized for reflectors with low focal length.

over diameter ratio, \( f/D \), which corresponds to a large half-subtended opening angle, \( \theta_e \), see Figure 2. Since many of the EVN telescopes are reflectors with high \( f/D \), we include a feed system over 4.4–15.5 GHz designed for the Onsala 20-m telescope to compare.

In this paper we use measured feed beam patterns for the current OTT QRFH over 3–18 GHz and for the SKA Band B QRFH over 4.6–24 GHz. The feed beam patterns for the BRAND QRFH over 1.5–15.5 GHz and the 4.4–15.5 GHz system for Onsala 20-m telescope are simulated. The measured patterns show good agreement with simulated. The patterns are used in the system simulator for the full telescope beam pattern simulations described in the next section.

### 2 Analysis

In the analysis we compare four different reflector geometries that are illustrated in Figure 3. The corresponding \( \theta_e \) are highlighted in Figure 2 with the largest being \( \theta_e = 79.61^\circ \) for the prime-focus reflector and the Cassegrain dual-reflector the smallest \( \theta_e = 6.09^\circ \). The Gregorian ring-focus (VGOS) represents \( \theta_e = 65^\circ \) and the Gregorian offset \( \theta_e = 58^\circ \).

For accurate SEFD analysis we use a full system simulator [5] that uses physical optics (PO) + physical theory of diffraction (PTD) to calculate the full telescope beam pattern, \( G(\theta, \phi, f) \). The telescope reflector is fed with either simulated or measured feed beam patterns. The full telescope beam pattern is used to weight the surrounding sky noise temperature, \( T(\theta, \phi, f) \), in a full-sphere integration to calculate the antenna noise temperature, \( T_A \), see Equation 1. One key component in \( T_A \) is the amount of spill-over noise picked up from the 300 K ground noise temperature.

\[
T_A = \frac{\int \int 4\pi G(\theta, \phi, f)T(\theta, \phi, f) \sin \theta \, d\theta \, d\phi}{\int \int 4\pi G(\theta, \phi, f) \sin \theta \, d\theta \, d\phi}. \tag{1}
\]

For the feed models analyzed in this paper a very high radiation efficiency is achieved. Therefore we assume a simple model for the total system noise: \( T_{sys} = T_A + T_{REC} \). \( T_{REC} \) represents the noise of the complete receiver chain. In Figure 4 we present two different re-
receiver setups measured with Y-factor tests in Onsala that show good noise performance over wide frequency bandwidth.

From the telescope main-beam gain, $G$, we can calculate the effective area of the reflector as $A_{eff} = (G\lambda^2)/(4\pi)$. Finally, it is straightforward to calculate SEFD according to

$$SEFD = \frac{2k_B T_{sys}}{A_{eff}},$$

where $k_B$ is the Boltzmann constant. For accurate estimation we include appropriate degradation of SEFD due to the aperture blockage for the respective reflector geometry (not applicable for offset reflectors).

## 3 Wideband System Performance

In Figure 5 we present simulated aperture efficiency, $\eta_a = A_{eff}/A_{phy}$, of the receiver systems on different reflectors. $A_{phy}$ is the available physical area of the reflector. The 10.3:1 feed was successfully designed for the prime-focus configuration with a challenging $\theta_e = 79.61^\circ$ to illuminate. Therefore, in the VGOS reflector at the low-frequency end it is over-illuminating (lower $\eta_a$) but matches better at high frequency when the feed beamwidth is slightly narrowed. The 5.2:1 feed show fairly smooth $\eta_a$ over bandwidth in the VGOS reflector. In Figure 6 we present the simulated SEFD at elevation $\theta = 30^\circ$ for the wideband systems applicable to the VGOS reflector. Simulation of one of the current OTT receivers is represented with the green dash-dotted line over 3–18 GHz. An alternative 5.2:1 system is presented over 3.5–18 GHz for a possible mitigation of RFI below the 3.5 GHz. Due to the waveguide structure of the QRFH feed, it acts as a high-pass filter for frequencies below the cut-off. The receiver systems show excellent simulated SEFD performance where the ones with less than decade bandwidth show SEFD better than 1,000 Jy over most of the respective frequency band.

Another interesting aspect of these receiver systems is how the performance scales with size of the main reflector. Within the EVN, main-reflector diameters range up to 100 m. The OTT VGOS reflector measures 13.2 m, whilst the SKA offset Gregorian reflector is 15 m in effective diameter. SEFD scales inversely proportional to $A_{eff} = \eta_a A_{phy}$ (Equation 2). The physical main-reflector area can be written $A_{phy} = \pi(D_m/2)^2$ where $D_m$ is the main-reflector diameter. In Figure 7 and Figure 8 we present SEFD as a contour plot over frequency and telescope main-reflector diameter, for the different receiver systems on different reflectors. The homogeneously dark red colored area represents SEFD higher than 2,100 Jy and does not fulfill VGOS specifications. For the VGOS type reflector in Figure 7 the 4.6–24 GHz system is on equal or better than the 3–18 GHz receiver on OTT, for overlapping frequencies. As mentioned, the higher cut-off frequency at 4.6 GHz mitigates potential LNA saturation from
the lower bands whilst the inclusion of the water-line at 22 GHz within the band introduces another possibility. In [6] we investigate theoretically this receiver system as a potential line-of-sight water vapor radiometer on the telescope. From simulation results, we expect a performance close to that of the dedicated water vapor radiometers of today. The obvious benefit is to have accurate water vapor measurements in the telescope line-
of-sight during observations with no separate system needed.

In general the receiver systems simulate better than specification on reflector diameters of 10–13 m for the Gregorian ring-focus type used in VGOS. The 1.5–15.5 GHz system can achieve similar SEFD for a 15-m dish in both Gregorian ring-focus and prime-focus reflectors, see middle plot in Figures 7 and 8, respectively. The best SEFD using the smallest reflector diameter is found in the highly shaped offset Gregorian reflector in the bottom row of Figure 8. This is expected as the feed is optimized specifically for this low-spillover reflector. For the Cassegrain dual-reflector system shown in the top row of Figure 8 the required reflector diameter is larger to achieve the same SEFD. This is due to the difficulty in designing feeds for a small $\theta_e$ over a large bandwidth without sacrificing aperture efficiency $\eta_a$. This type of feed in a standard horn configuration generally needs to be very large, which makes it difficult to fit in the receiver cabin as well. However, this result shows good performance over the 3.5:1 bandwidth which overlaps with VGOS frequencies. This configuration also has a higher cut-off frequency to mitigate low-frequency RFI pollution and is suitable for reflectors with small $\theta_e$, which is common within the EVN. The frequency band available would allow for joint VLBI observations with VGOS.

### 4 Conclusions

We present different receiver systems applicable especially to the VGOS-type Gregorian ring-focus reflector. The presented receiver systems are evaluated through simulation with respect to main-reflector diameter and bandwidth for VGOS and other common reflector geometries. The 4.6–24 GHz allows for an interesting upgrade option in future VGOS receivers with a less RFI-polluted frequency band. SEFD performance can be expected in the same order as current VGOS systems, with the possibility of line-of-sight WVR in parallel with observation (further studied in [6]). A receiver system overlapping VGOS frequencies and suitable for Cassegrain dual-reflectors with high $f/D$ (e.g., EVN) was also presented and evaluated. Finally we include the 10.3:1 receiver developed for radio astronomy (BRAND) over 1.5–15.5 GHz. This option enables a decade in available bandwidth with a substantial overlap with VGOS frequencies, further enabling joint observations between these systems.
