Abstract

This paper presents the verification of a generational copying garbage collector for the CakeML runtime system. The proof is split into an algorithm proof and an implementation proof. The algorithm proof follows the structure of the informal intuition for the generational collector's correctness, namely, a partial collection cycle in a generational collector is the same as running a full collection on part of the heap, if one views pointers to old data as non-pointers. We present a pragmatic way of dealing with ML-style mutable state, such as references and arrays, in the proofs. The development has been fully integrated into the in-logic bootstrapped CakeML compiler, which now includes command-line arguments that allow configuration of the generational collector. All proofs were carried out in the HOL4 theorem prover.

Keywords Interactive theorem proving · Formal methods · Garbage collection · Compiler verification

1 Introduction

High-level programming languages such as ML, Haskell, Java, Javascript and Python provide an abstraction of memory which removes the burden of memory management from the application programmer. The most common way to implement this memory abstraction is to use garbage collectors in the language runtimes. The garbage collector is a routine which is invoked when the memory allocator finds that there is not enough free space to perform allocation. The collector's purpose is to produce new free space. It does so by traversing the data in memory and deleting data that is unreachable from the running application. There are two classic algorithms: mark-and-sweep collectors mark all live objects and delete the others; copying collectors copy all live objects to a new heap and then discard the old heap and its dead objects.

Since garbage collectors are an integral part of programming language implementations, it is essential that they are performant. As a result, there have been numerous improvements

to the classic algorithms mentioned above. There are variants of the classic algorithms that make them incremental (do a bit of garbage collection often), generational (run the collector only on recent data in the heap), or concurrent (run the collector as a separate thread alongside the program).

This paper's topic is the verification of a generational copying collector for the CakeML compiler and runtime system [18]. The CakeML project has produced a formally verified compiler for an ML-like language called CakeML. The compiler produces binaries that include a verified language runtime, with supporting routines such as an arbitrary precision arithmetic library and a garbage collector. One of the main aims of the CakeML compiler project is to produce a verified system that is as realistic as possible. This is why we want the garbage collector to be more than just an implementation of one of the basic algorithms.

Contributions

- To the best of our knowledge, this paper presents the first completed formal verification of a generational garbage collector. However, it seems that the CertiCoq project [1] is in the process of verifying a generational garbage collector.
- We present a pragmatic approach to dealing with mutable state, such as ML-style references and arrays, in the context of implementation and verification of a generational garbage collector. Mutable state adds a layer of complexity since generational collectors need to treat pointers from old data to new data with special care. The CertiCoq project does not include mutable data, i.e. their setting is simpler than ours in this respect.
- We describe how the generational algorithm can be verified separately from the concrete implementation. Furthermore, we show how the proof can be structured so that it follows the intuition of informal explanations of the form: a partial collection cycle in a generational collector is the same as running a full collection on part of the heap if one views pointers to old data as non-pointers.
- This paper provides more detail than any previous CakeML publication on how algorithm-level proofs can be used to write and verify concrete implementations of garbage collectors for CakeML, and how these are integrated into the full CakeML compiler and runtime. The updated in-logic bootstrapped compiler comes with new command-line arguments that allow configuration of the generational garbage collector.

Differences from Conference Version This paper extends a previous conference paper [4] by providing more detailed explanations, a new section on timing the new GC, and stronger theorems about the GC algorithms. Explanations have been expanded in Sects. 3.2, 3.3, and, in particular, Sect. 4. The new timing section (Sect. 5) compares the generational garbage collector with the previous non-generational version. In Sect. 3.3, the correctness theorems have been strengthened to cover GC completeness, i.e., that a collection cycle collects all garbage.

2 Approach

In this section, we give a high-level overview of the work and our approach to it. Subsequent sections will cover these topics in more detail.

Algorithm-Level Modelling and Verification

- The intuition behind the copying garbage collection is important in order to understand this paper. Section 3.1 provides an explanation of the basic Cheney copying collector

algorithm. Section 3.2 continues with how the basic algorithm can be modified to run as a generational collector. It also describes how we deal with mutable state such as ML-style references and arrays.

- Section 3.3 describes how the algorithm has been modelled as HOL functions. These algorithm-level HOL functions model memory abstractly, in particular we use HOL lists to represent heap segments. This representation neatly allows us to avoid awkward reasoning about potential overlap between memory segments in the algorithm-level proofs. It also works well with the separation logic we use later to map the abstract heaps to their concrete memory representations, in Sect. 4.2.
- Section 3.4 defines the main correctness property, `gc_related`, that any garbage collector must satisfy: for every pointer traversal that exists in the original heap from some root (i.e. program variable), there must be a similar pointer traversal possible in the new heap.
- A generational collector can run either a partial collection, which collects only some part of the heap, or a full collection of the entire heap. We show that the full collection satisfies `gc_related`. To show that a run of the partial collector also satisfies `gc_related`, we exploit a simulation argument that allows us to reuse the proofs for the full collector. Intuitively, a run of the partial collector on a heap segment `h` simulates a run of the full collector on a heap containing only `h`. Section 3.4 provides some details on this.

Implementation and Integration into the CakeML Compiler

- The CakeML compiler goes through several intermediate languages on the way from source syntax to machine code. The garbage collector is introduced gradually in the intermediate languages `DATALANG` (abstract data), `WORDLANG` (machine words, concrete memory, but abstract stack) and `STACKLANG` (more concrete stack).
- The verification of the compiler phase from `DATALANG` to `WORDLANG` specifies how abstract values of `DATALANG` are mapped to instantiations of the heap types that the algorithm-level garbage collection operates over, Sect. 4.1. We prove that `gc_related` implies that from `DATALANG`'s point of view, nothing changes when a garbage collector is run.
- For the verification of the `DATALANG` to `WORDLANG` compiler, we also specify how each instantiation of the algorithm-level heap types maps into `WORDLANG`'s concrete machine words and memory, Sect. 4.2. Here we implement and verify a *shallow embedding* of the garbage collection algorithm. This shallow embedding is used as a primitive by the semantics of `WORDLANG`.
- Further down in the compiler, the garbage collection primitive needs to be implemented by a *deep embedding* that can be compiled with the rest of the code. This happens in `STACKLANG`, where a compiler phase attaches an implementation of the garbage collector to the currently compiled program and replaces all occurrences of `Alloc` by a call to the new routine. Implementing the collector in `STACKLANG` is tedious because `STACKLANG` is very low-level—it comes after instruction selection and register allocation. However, the verification proof is relatively straight-forward since the proof only needs to show that the `STACKLANG` deep embedding computes the same function as the shallow embedding mentioned above.
- Finally, the CakeML compiler's in-logic bootstrap needs updating to work with the new garbage collection algorithm. The bootstrap process itself does not need much updating, illustrating the resilience of the bootstrapping procedure to such changes. We extend the bootstrapped compiler to recognise command-line options specifying which garbage collector is to be generated: `-gc=none` for no garbage collector; `-gc=simple` for the previous non-generational copying collector; and `-gc=gensize` for the generational collector described in the present paper. Here *size* is the size of the nursery generation in number

of machine words. With these command-line options, users can generate a binary with a specific instance of the garbage collector installed.

Mechanised Proofs The development was carried out in HOL4. The sources are available at <http://code.cakeml.org/>. The algorithm and its proofs are under `compiler/backend/gc`; the first implementation at the word-level, i.e. the shallow embedding, is in `compiler/backend/proofs/word_gcFunctionsScript.sml` and its verification is in `compiler/backend/proofs/data_to_word_gcProofScript.sml`; the STACKLANG deep embedding is in `compiler/backend/stack_allocScript.sml`; its verification is in `compiler/backend/proofs/stack_allocProofScript.sml`.

Terminology The *heap* is the region of memory where heap elements are allocated and which is to be garbage collected. A *heap element* is the unit of memory allocation. A heap element can contain pointers to other heap elements. The collection of all program visible variables is called the *roots*.

3 Algorithm Modelling and Verification

Garbage collectors are complicated pieces of code. As such, it makes sense to separate the reasoning about algorithm correctness from the reasoning about the details of its more concrete implementations. Such a split also makes the algorithm proofs more reusable than proofs that depend on implementation details. This section focuses on the algorithm level.

3.1 Intuition for Basic Algorithm

Intuitively, a Cheney copying garbage collector copies the live elements from the current heap into a new heap. We will call the heaps old and new. In its simplest form, the algorithm keeps track of two boundaries inside the new heap. These split the new heap into three parts, which we will call *h1*, *h2*, and *unused* space.

Throughout execution, all pointers in the heap segment *h1* will point to the new heap, and all pointers in heap segment *h2* will only point to the old heap, i.e. pointers that are yet to be processed.

The algorithm's most primitive operation is to move a pointer *ptr*, and the data element *d* that *ptr* points at, from the old heap to the new one. The move primitive's behaviour depends on whether *d* is a *forwarding pointer* or not. A forwarding pointer is a heap element with a special tag to distinguish it from other heap elements. Forwarding pointers will only ever occur in the heap if the garbage collector puts them there; between collection cycles, they are never present nor created.

If *d* is not a forwarding pointer, then *d* will be copied to the end of heap segment *h2*, consuming some of the unused space, and *ptr* is updated to be the address of the new location of *d*. A forwarding pointer to the new location is inserted at the old location of *d*, namely at the original value of *ptr*. We draw forwarding pointers as hollow boxes with dashed arrows illustrating where they point. Solid arrows that are irrelevant for the example are omitted in these diagrams.

Before move of ptr:

After move of ptr:

If d is already a forwarding pointer, the move primitive knows that this element has been moved previously; it reads the new pointer value from the forwarding pointer, and leaves the memory unchanged.

The algorithm starts from a state where the new heap consists of only free space. It then runs the move primitive on each pointer in the list of roots. This processing of the roots populates $h2$.

Once the roots have been processed, the main loop starts. The main loop picks the first heap element from $h2$ and applies the move primitive to each of the pointers that that heap element contains. Once the pointers have been updated, the boundary between $h1$ and $h2$ can be moved, so that the recently processed element becomes part of $h1$.

Before iteration of main loop:

After iteration of main loop:

This process is repeated until $h2$ becomes empty, and the new heap contains no pointers to the old heap. The old heap can then be discarded, since it only contains data that is unreachable from the roots. The next time the garbage collector runs, the previous old heap is used as the new heap.

3.2 Intuition for Generational Algorithm

Generational garbage collectors switch between running *full* and *partial* collection cycles. In a partial collection cycle, we run the collector only on part of the heap. The motivation is that new data tends to be short-lived while old data tends to stay live. By running the collector on new data only, one avoids copying around old data unnecessarily. Full collection cycles consider the entire heap; hence they are slower, but can potentially free up more space.

The intuition is that a partial collection focuses on a small segment of the full heap and ignores the rest, but operates as a normal full collection on this small segment. The cleanup

after a partial collection cycle differs from a Cheney copying collector: of course, we cannot simply discard the old heap, since it may still contain live data outside the current segment. Rather, we copy the new segment back into its previous location in the old heap.

Partial collection pretends that a small part is the entire heap:

The collector operates as normal on part of heap:

Finally, the external new segment is copied back:

For the partial collection to work we need:

- the partial algorithm to treat all pointers to the outside (old data) as non-pointers, in order to avoid copying old data into its new memory region.
- that outside data does not point into the currently collected segment of the heap, because the partial collector should be free to move around and delete elements in the segment it is working on without looking at the heap outside.

In ML programs, most data is immutable, which means that old data cannot point at new data. However, ML programs also use references and arrays (henceforth both will be called references) that are mutable. References are usually used sparingly, but are dangerous for a generational garbage collector because they can point into the new data from old data.

Our pragmatic solution is to make sure immutable data is allocated from the bottom of the heap upwards, and references are allocated from the top downwards, i.e. the memory layout as in the diagram below. (The conventional solution, which does not impose such a layout on the heap, is described further down.)

The following diagram also shows our use of a *GC trigger pointer* which indicates the end of the current nursery generation. Any allocation that tries to grab memory past the GC trigger pointer causes the GC to run. By default, after a GC run, the GC trigger pointer is placed the distance of the nursery generation into the unused part of the heap. If the allocation asks for more space than the length of the nursery size, then the trigger pointer is placed further into the unused part of the heap in order to guarantee success of the allocation.

To satisfy requirement (a), full collection cycles must maintain this memory layout. Hence our full collection is the simple garbage collection algorithm described in the previous section, modified so that it copies references to the end of the new heap and immutable data to the start. The algorithm assumes that we have a way to distinguish references from other data

elements; the CakeML compiler delivers on this assumption by way of tag bits. To satisfy requirement (b), we make each run of the partial collection algorithm treat the references as roots that are not part of the heap.

Our approach means that references will never be collected by a partial collection. However, they will be collected when the full collection is run.

Full collections happen if there is a possibility that the partial collector might fail to free up enough space, i.e. if the amount of unused space prior to collection is less than the amount of new memory requested. Note that there is no heuristic involved here: if there is enough space for the allocation between the GC trigger pointer and the actual end of the heap, then a partial collection is performed since the partial collection will, in this case, always be able to move the GC trigger pointer a sufficient distance towards the beginning of the references for the requested allocation to be successful.

One could run a partial collection regardless of whether it might fail to find enough memory, and then run a full collection if it fails. We decided against this because scanning all of the roots twice would potentially be costly and if the complete heap is so close to running out of space that a partial collection might fail, then a full collection is likely to run very soon anyway.

Reconfiguring or Switching GC at Runtime With our approach, it is possible to reconfigure or switch GC at runtime. One can at any point switch from the generational to the non-generational because the non-generational version does not care about where the references are. Switching from the non-generational to the generational GC can be done by running a full collection cycle of the generational corrector on the heap. This works because the full collection cycle of the generational collector moves the references to the top of the heap regardless of where they were before.

The Conventional Solution to Mutable References Most implementations of ML do not impose a heap layout where references are at one end of a heap. Instead they use write barriers on reference updates. In the simplest form, an approach based on write barriers executes code at every reference update that conses the name of the updated reference to a list of references that have been updated since the last run of the generational garbage collector. With such a record of which references have been updated, the partial collector can use just a subset of the references (only the relevant ones) as extra roots. This is in contrast to our approach which treats all references as extra roots always.

We decided to go with the simple but unconventional approach of imposing a heap layout because it is simpler for the verification proofs, but also because we do not want to allocate write barriers on reference updates. Maintaining a list of recently updated references is not needed for the non-generational collector, and we want to have the same mutator code for both the generational and non-generational collectors in order to be able to switch between them.

3.3 Formalisation

The algorithm-level formalisation represents heaps abstractly as lists, where each element is of type `heap_element`. The definition of `heap_element` is intentionally somewhat abstract, with type variables α used for the type of data that can be attached to pointers and data elements, and β which represents tags carried by pointers. We use this flexibility to verify the partial collector for our generational version, in the next section.

Addresses are of type `heap_address` and can either be an actual pointer with some data attached, or a non-pointer `Data`. A heap element can be unused space (`Unused`), a forwarding pointer (`ForwardPointer`), or actual data (`DataElement`).

$$\begin{aligned} \alpha \text{ heap_address} &= \text{Pointer num } \alpha \mid \text{Data } \alpha \\ (\alpha, \beta) \text{ heap_element} &= \\ &\quad \text{Unused num} \\ &\quad \mid \text{ForwardPointer num } \alpha \text{ num} \\ &\quad \mid \text{DataElement } (\alpha \text{ heap_address list}) \text{ num } \beta \end{aligned}$$

Each heap element carries its concrete length in machine words (minus one). The length (minus one) is part of each element for the convenience of defining a length function, `el_length`. No heap element has a zero length.

$$\begin{aligned} \text{el_length (Unused } l) &= l + 1 \\ \text{el_length (ForwardPointer } n \text{ d } l) &= l + 1 \\ \text{el_length (DataElement xs l data)} &= l + 1 \end{aligned}$$

The natural number (type `num` in HOL) in Pointer values is an offset from the start of the relevant heap. We define a lookup function `heap_lookup` that fetches the content of address a from a heap xs :

$$\begin{aligned} \text{heap_lookup } a \text{ []} &= \text{None} \\ \text{heap_lookup } a \text{ (x::xs)} &= \\ &\quad \text{if } a = 0 \text{ then Some } x \\ &\quad \text{else if } a < \text{el_length } x \text{ then None} \\ &\quad \text{else heap_lookup } (a - \text{el_length } x) \text{ xs} \end{aligned}$$

The generational garbage collector has two main routines: `gen_gc_full` which runs a collection on the entire heap including the references, and `gen_gc_partial` which runs only on part of the heap, treating the references as extra roots. Both use the record type `gc_state` to represent the heaps. In a state s , the old heap is in $s.\text{heap}$, and the new heap comprises the following fields: $s.h1$ and $s.h2$ are the heap segments $h1$ and $h2$ from before, $s.n$ is the length of the unused space, and $s.r2, s.r1$ are for references what $s.h1$ and $s.h2$ are for immutable data¹; $s.ok$ is a boolean representing whether s is a well-formed state that has been arrived at through a well-behaved execution. It has no impact on the behaviour of the garbage collector; its only use is in proofs, where it serves as a convenient trick to propagate invariants downwards in refinement proofs. Intuitively, adding a conjunct to $s.ok$ is similar in spirit to making an assert statement in a program.

Figure 1 shows the HOL function implementing the move primitive for the partial generational algorithm. It follows what was described informally in the section above: it does nothing when applied to a non-pointer, or to a pointer that points outside the current generation. When applied to a pointer to a forwarding pointer, it follows the forwarding pointer but leaves the heap unchanged. When applied to a pointer to some data element d , it inserts d at the end of $h2$, decrements the amount of unused space by the length of d , and inserts, at the old location of d , a forwarding pointer to its new location. When applied to an invalid pointer (i.e. to an invalid heap location, or to a location containing unused space) it does nothing except set the `ok` field of the resultant state to false; we prove later that this never happens.

¹ For technical reasons, the segments $s.r1$ and $s.r2$ each comprise two distinct heap segments that are treated slightly differently; the presentation here abstracts away from this detail.

```

gen_gc_partial_move conf state (Data d) = (Data d, state)
gen_gc_partial_move conf state (Pointer ptr d) =
  let ok = state.ok  $\wedge$  ptr < heap_length state.heap in
  if ptr < conf.gen_start  $\vee$  conf.refs.start  $\leq$  ptr then
    (Pointer ptr d, state with ok := ok)
  else
    case heap_lookup ptr state.heap of
    | None  $\Rightarrow$  (Pointer ptr d, state with ok := F)
    | Some (Unused _)  $\Rightarrow$  (Pointer ptr d, state with ok := F)
    | Some (ForwardPointer ptr' l')  $\Rightarrow$  (Pointer ptr' d, state)
    | Some (DataElement xs l dd)  $\Rightarrow$ 
      let ok = ok  $\wedge$  l + 1  $\leq$  state.n  $\wedge$   $\neg$ conf.isRef dd;
      n = state.n - (l + 1);
      h2 = state.h2 + [DataElement xs l dd];
      (heap, ok) = write_forward_pointer ptr state.heap state.a d ok;
      a = state.a + l + 1 in
      (Pointer state.a d,
       state with  $\langle$ h2 := h2; n := n; a := a; heap := heap; ok := ok $\rangle$ )

```

Fig. 1 The algorithm implementation of the move primitive for `gen_gc_partial`

The `with` notation is for record update: for example, s with $\langle ok := T; h2 := l \rangle$ denotes a record that is as s but with the `ok` and `h2` fields updated to the given values.

The HOL function `gen_gc_full_move` implements the move primitive for the full generational collection. Its definition, which is shown in Fig. 2, is similar to `gen_gc_partial_move`, but differs in two main ways. First, `gen_gc_full_move` does not consider generation boundaries. Second, in order to maintain the memory layout it must distinguish between pointers to references and pointers to immutable data, allocating references at the end of the new heap's unused space and immutable data at the beginning. This is implemented by the case split on `conf.isRef`, which is an oracle for determining whether a data element is a reference or not. It is kept abstract for the purposes of the algorithm-level verification; when we integrate our collector into the CakeML compiler, we instantiate `conf.isRef` with a function that inspects the tag bits of the data element.

`gen_gc_partial_move` does not need to consider pointers to references, since generations are entirely contained in the immutable part of the heap.

The algorithms for an entire collection cycle consist of several HOL functions in a similar style; the functions implementing the move primitive are the most interesting of these. The main responsibility of the others is to apply the move primitive to relevant roots and heap elements, following the informal explanations in previous sections.

3.4 Verification

For each collector (`gen_gc_full` and `gen_gc_partial`), we prove that they do not lose any live elements. We formalise this notion with the `gc_related` predicate shown below. If a collector can produce $heap_2$ from $heap_1$, there must be a map f such that `gc_related` f $heap_1$ $heap_2$. The intuition is that if there was a heap element at address a in $heap_1$ that was retained by the collector, the same heap element resides at address $f a$ in $heap_2$.

The conjuncts of the following definition state, respectively: that f must be an injective map into the set of valid addresses in $heap_2$; that its domain must be a subset of the valid addresses into $heap_1$; and that for every data element D at address $i \in \text{domain } f$, every address reachable from D is also in the domain of f , and $f i$ points to a data element that is exactly D with all its pointers updated according to f .

```

gen_gc_full_move conf state (Data d) = (Data d, state)
gen_gc_full_move conf state (Pointer ptr d) =
  case heap_lookup ptr state.heap of
  | None  $\Rightarrow$  (Pointer ptr d, state with ok := F)
  | Some (Unused _)  $\Rightarrow$  (Pointer ptr d, state with ok := F)
  | Some (ForwardPointer ptr' _)  $\Rightarrow$  (Pointer ptr' d, state)
  | Some (DataElement xs l dd)  $\Rightarrow$ 
    let ok = state.ok  $\wedge$  l + 1  $\leq$  state.n; n = state.n - (l + 1)
    in
      if conf.isRef dd then -- Does the data have a reference tag?
        let r2 = DataElement xs l dd::state.r2; -- References to the front of r2
        (heap, ok) = write_forward_pointer ptr state.heap (state.a + n) d ok
        in
          (Pointer (state.a + n) d,
            state with  $\langle$ r2 := r2; n := n; heap := heap; ok := ok $\rangle$ )
      else -- Other data to the end of h2
        let h2 = state.h2  $\#$  [DataElement xs l dd];
        (heap, ok) = write_forward_pointer ptr state.heap state.a d ok;
        a = state.a + l + 1
        in
          (Pointer state.a d,
            state with  $\langle$ h2 := h2; n := n; a := a; heap := heap; ok := ok $\rangle$ )

```

Fig. 2 The algorithm implementation of the move primitive for `gen_gc_full`

$$\begin{aligned}
& \text{gc_related } f \text{ heap}_1 \text{ heap}_2 \iff \\
& \text{injective } (\text{apply } f) \text{ (domain } f) \{ a \mid \text{isSomeDataElement } (\text{heap_lookup } a \text{ heap}_2) \} \wedge \\
& (\forall i. i \in \text{domain } f \Rightarrow \text{isSomeDataElement } (\text{heap_lookup } i \text{ heap}_1)) \wedge \\
& \forall i \text{ xs } l \text{ d.} \\
& \quad i \in \text{domain } f \wedge \text{heap_lookup } i \text{ heap}_1 = \text{Some } (\text{DataElement } xs \text{ l } d) \Rightarrow \\
& \quad \text{heap_lookup } (\text{apply } f \text{ } i) \text{ heap}_2 = \\
& \quad \text{Some } (\text{DataElement } (\text{addr_map } (\text{apply } f) \text{ xs}) \text{ l } d) \wedge \\
& \quad \forall ptr \text{ u. mem } (\text{Pointer } ptr \text{ u}) \text{ xs} \Rightarrow ptr \in \text{domain } f
\end{aligned}$$

Proving a `gc_related`-correctness result for `gen_gc_full`, as below, is a substantial task that requires a non-trivial invariant, similar to the one we presented in earlier work [12]. The main correctness theorem is as follows. We will not give further details of its proofs in this paper; for such proofs see [12].

$$\begin{aligned}
& \vdash \text{roots_ok roots heap} \wedge \text{heap_ok heap conf.limit} \Rightarrow \\
& \quad \exists \text{state } f. \\
& \quad \text{gen_gc_full conf (roots, heap)} = (\text{addr_map } (\text{apply } f) \text{ roots, state}) \wedge \\
& \quad \text{domain } f = \text{reachable_addresses roots heap} \wedge \\
& \quad \text{heap_length } (\text{state.h1} \# \text{state.r1}) = \text{heap_length } (\text{heap_filter } (\text{domain } f) \text{ heap}) \\
& \quad \wedge \text{gc_related } f \text{ heap } (\text{state.h1} \# \text{heap_expand state.n} \# \text{state.r1})
\end{aligned}$$

The theorem above can be read as saying: if all roots are pointers to data elements in the heap (abbreviated `roots_ok`), if the heap has length `conf.limit`, and if all pointers in the heap are valid non-forwarding pointers back into the heap (abbreviated `heap_ok`), then a call to `gen_gc_full` results in a state that is `gc_related` via a mapping `f` whose domain is exactly all the addresses that are reachable from `roots` in the original `heap`. The theorem above, furthermore, states that the length of the used parts of the heap (i.e. `state.h1` and `state.r1`) is the same as

the sum of the lengths of all reachable data elements in the original heap. The latter property means that a full collection cycle is complete in the sense that it collects all garbage.

The more interesting part is the verification of `gen_gc_partial`, which we conduct by drawing a formal analogy between how `gen_gc_full` operates and how `gen_gc_partial` operates on a small piece of the heap. The proof is structured in two steps:

1. We first prove a simulation result: running `gen_gc_partial` is the same as running `gen_gc_full` on a state that has been modified to pretend that part of the heap is not there and the references are extra roots.
2. We then show a `gc_related` result for `gen_gc_partial` by carrying over the same result for `gen_gc_full` via the simulation result (without the completeness conjunct, since partial cycles are not complete).

For the simulation result, we instantiate the type variables in the `gen_gc_full` algorithm so that we can embed pointers into Data blocks. The idea is that encoding pointers to locations outside the current generation as Data causes `gen_gc_full` to treat them as non-pointers, mimicking the fact that `gen_gc_partial` does not collect there. The type we use for this purpose is defined as follows:

$$(\alpha, \beta) \text{ data_sort} = \text{Protected } \alpha \mid \text{Real } \beta$$

and the translation from `gen_gc_partial`'s pointers to pointers on the pretend-heap used by `gen_gc_full` in the simulation argument is:

```
to_gen_heap_address conf (Data a) = Data (Real a)
to_gen_heap_address conf (Pointer ptr a) =
  if ptr < conf.gen_start then Data (Protected (Pointer ptr a))
  else if conf.refs_start ≤ ptr then Data (Protected (Pointer ptr a))
  else Pointer (ptr - conf.gen_start) (Real a)
```

Similar to `to_gen` functions, elided here, encode the roots, heap, state and configuration for a run of `gen_gc_partial` into those for a run of `gen_gc_full`. We prove that for every execution of `gen_gc_partial` starting from an ok state, and the corresponding execution of `gen_gc_full` starting from the encoding of the same state through the `to_gen` functions, encoding the results of the former with `to_gen` yields precisely the results of the latter.

Initially, we made an attempt to do the `gc_related` proof for `gen_gc_partial` using the obvious route of manually adapting all loop invariants and proofs for `gen_gc_full` into invariants and proofs for `gen_gc_partial`. This soon turned out to overly cumbersome; hence we switched to the current approach because it seemed more expedient and more interesting. As a result, the proofs for `gen_gc_partial` are more concerned with syntactic properties of the `to_gen`-encodings than with semantic properties of the collector. The syntactic arguments are occasionally quite tedious, but we believe this approach still leads to more understandable and less repetitive proofs.

Finally, note that `gc_related` is the same correctness property that we use for the previous copying collector; this makes it straightforward to prove that the top-level correctness theorem of the CakeML compiler remains true if we swap out the garbage collector.

3.5 Combining the Partial and Full Collectors

An implementation that uses the generational collector will mostly run the partial collector and occasionally the full one. At the algorithm level, we define a combined collector and leave

it up to the implementation to decide when a partial collection is to be run. The choice is made visible to the implementation by having a boolean input `do_partial` to the combined function. The combined function will produce a valid heap regardless of the value of `do_partial`.

Our CakeML implementation (next section) runs a partial collection if the allocation will succeed even if the collector does not manage to free up any space, i.e., if there is already enough space on the other side of the GC trigger pointer before the GC starts (Sect. 3.2).

4 Implementation and Integration into the CakeML Compiler

The concept of garbage collection is introduced in the CakeML compiler at the point where a language with unbounded memory (DATA_{LANG}) is compiled into a language with a finite memory (WORD_{LANG}). In this phase of the compiler, we have to prove that the garbage collector automates memory deallocation and implements the illusion of an unbounded memory.

A key lemma is the proof that running WORD_{LANG}'s allocation routine (which includes the GC) preserves all important invariants and that the resulting WORD_{LANG} state relates to the same DATA_{LANG} state extended with the requested new space (or alternatively giving up with a `NotEnoughSpace` exception). This theorem is shown in Fig. 9. It is used as a part in the correctness proof of the DATA_{LANG}-to-WORD_{LANG} phase of the compiler: theorem shown in Fig. 10.

Proving the key lemma about allocation requires several layers of invariants in the form of state- and value-relations and proofs about these. These invariants are the topic of the following subsections. The last part of this section will also briefly describe the required work in a language further down in the compiler (STACK_{LANG}) where the GC primitive is implemented in concrete code.

4.1 Representing Values in the Abstract Heap

The language which comes immediately prior to the introduction of the garbage collector, DATA_{LANG}, stores values of type `v` in its variables.

$$v = \text{Number int} \mid \text{Word64 (64 word)} \mid \text{Block num (v list)} \\ \mid \text{CodePtr num} \mid \text{RefPtr num}$$

DATA_{LANG} gets compiled into a language called WORD_{LANG} where memory is finite and variables are of type `word_loc`. A `word_loc` is either a machine word `Word w` where the cardinality of α encodes the word width,² or a code location `Loc l1 l2`, where l_1 is the function name and l_2 is the label within that function.

$$\alpha \text{ word_loc} = \text{Word } (\alpha \text{ word}) \mid \text{Loc num num}$$

In what follows, we will provide some of the definitions that specify how values of type `v` are represented in WORD_{LANG}'s `word_loc` variables and memory. The definitions are multi-layered and somewhat verbose. In order to make sense of the definitions, we will use the following DATA_{LANG} value as a running example.

Block 3 [Number 5; Number 80000000000000]

² For details on this representation of words and word widths, we refer to Harrison [7].

The relationship between values of type v and `WORDLANG` is split into layers. We first relate v to an instantiation of the data abstraction used by the algorithm-level verification of the garbage collector, and then separately in the next section relate that layer down to `word_loc` and concrete memory.

The relation v_inv , shown in Fig. 3, specifies how values of type v relate to the `heap_addresses` and heaps that the garbage collection algorithms operate on. The definition has a case for each value constructor in the type v . Note that $list_rel\ r\ l_1\ l_2$ is true iff l_1 and l_2 have equal length and their elements are pairwise related by r .

The `Number` case of v_inv is made complicated by the fact that `DATALANG` allows integers of arbitrary size. If an integer is small enough to fit into a tagged machine word, then the head address x must be `Data` that carries the value of the small integer, and there is no requirement on the heap. If an integer i is too large to fit into a machine word, then the heap address must be a `Pointer` to a heap location containing the data for the bignum representing integer i .

The `Word64` case of v_inv is simpler, because 64-bit words always need to be boxed. On 64-bit architectures, they are represented as a `DataElement` with a single word as payload. On 32-bit architectures (the only other alternative), they are represented as two words: one for each half of the 64-bit word. Here and throughout, $\dimindex\ (: \alpha)$ is the width of the word type αword (64 for 64-bit words), and $\dimword\ (: \alpha)$ is the size of the word type (2^{64} for 64-bit words). $(: \alpha)$ encodes the type α as a term.

The `CodePtr` case shows that `DATALANG`'s code pointers are represented directly as `Loc`-values wrapped in the `Data` constructor to signal that they are not pointers that the GC is to follow. The second element of the `Loc` is set to zero because `DATALANG`'s code pointers only point at the entry to functions.

The `RefPtr` case of v_inv makes use of the argument called f , which is a finite map that specifies how semantic location values for reference pointers are to be represented as addresses.

The `Block` case specifies how constructors and tuples from `DATALANG` are represented. Values without a payload (e.g. those coming from source values such as `[]`, `NONE`, `()`) are represented in a word wrapped as `Data`. All other `Block` values are represented as `DataElements` that carry the name n of the constructor that it represents. Constructor names are numbers at this stage of compilation.

Note that pointers representing `Block`-values carry information about the constructor name and the length of the payload in the `Pointer` itself. This information is stored there in order to make primitives used for pattern matching faster: in many cases a pattern match can look at only the pointer bits rather than load the address in order to determine whether there is a match. The amount of information stored in `Pointers` is determined by the configuration `conf`. The `ptr_bits` function (definition omitted here) determines the encoding of the information based on `conf`.

For our running example, we can expand v_inv as follows to arrive at a constraint on the heap: the address x must be a pointer to a `DataElement` which contains `Data` representing integer 5, and a pointer to some memory location which contains the machine words representing

```

v_inv conf (Number i) (x,f,heap)  $\iff$ 
  if small_int ( $\alpha$ ) i then x = Data (Word (Smallnum i))
  else
     $\exists$  ptr.
      x = Pointer ptr (Word 0w)  $\wedge$ 
      heap_lookup ptr heap = Some (Bignum i)

v_inv conf (Word64 w) (x,f,heap)  $\iff$ 
   $\exists$  ptr.
    x = Pointer ptr (Word 0w)  $\wedge$ 
    heap_lookup ptr heap = Some (Word64Rep ( $\alpha$ ) w)

v_inv conf (CodePtr n) (x,f,heap)  $\iff$ 
  x = Data (Loc n 0)

v_inv conf (RefPtr n) (x,f,heap)  $\iff$ 
  x = Pointer (apply f n) (Word 0w)  $\wedge$  n  $\in$  domain f

v_inv conf (Block n vs) (x,f,heap)  $\iff$ 
  if vs = [] then
    x = Data (Word (BlockNil n))  $\wedge$  n < dimword ( $\alpha$ ) div 16
  else
     $\exists$  ptr xs.
      list_rel ( $\lambda v x'. v\_inv\ conf\ v\ (x',f,heap)$ ) vs xs  $\wedge$ 
      x = Pointer ptr (Word (ptr_bits conf n (length xs)))  $\wedge$ 
      heap_lookup ptr heap = Some (BlockRep n xs)

Bignum i =
  let (sign,payload) = sign_and_words_of_integer i
  in
    DataElement [] (length payload) (NumTag sign,map Word payload)

BlockNil n = n2w n << 4 + 2w

BlockRep tag xs = DataElement xs (length xs) (BlockTag tag,[])

Word64Rep ( $\alpha$ ) w =
  if dimindex ( $\alpha$ ) < 64 then
    DataElement [] 2 (Word64Tag,[Word ((63 >< 32) w); Word ((31 >< 0) w)])
  else DataElement [] 1 (Word64Tag,[Word ((63 >< 0) w)])

```

Fig. 3 Relation between values of type *v* and abstract heaps

bignum 8000000000000000. Here we assume that we are talking about a 32-bit architecture. Below one can see that the first Pointer is given information, `ptr_bits conf 3 2`, about the length, 2, and tag, 3, of the Block that it points to.

$$\begin{aligned}
& \vdash v_inv \text{ conf } (\text{Block } 3 \text{ [Number } 5; \text{ Number } 8000000000000000]) (x.f, heap) \iff \\
& \quad \exists ptr_1 ptr_2. \\
& \quad \quad x = \text{Pointer } ptr_1 \text{ (Word (ptr_bits conf } 3 \text{ } 2))} \wedge \\
& \quad \quad \text{heap_lookup } ptr_1 \text{ heap} = \\
& \quad \quad \quad \text{Some} \\
& \quad \quad \quad (\text{DataElement [Data (Word (Smallnum } 5)); \text{ Pointer } ptr_2 \text{ (Word } 0w)] } 2 \\
& \quad \quad \quad (\text{BlockTag } 3, [])) \wedge \\
& \quad \quad \text{heap_lookup } ptr_2 \text{ heap} = \text{Some (Bignum } 8000000000000000)
\end{aligned}$$

The following is an instantiation of *heap* that satisfies the constraint set out by *v_inv* for representing our running example.

$$\begin{aligned}
& \vdash v_inv \text{ conf } (\text{Block } 3 \text{ [Number } 5; \text{ Number } 8000000000000000]) \\
& \quad (\text{Pointer } 0 \text{ (Word (ptr_bits conf } 3 \text{ } 2))}f, \\
& \quad [\text{DataElement [Data (Word (Smallnum } 5)); \text{ Pointer } 3 \text{ (Word } 0w)] } 2 \\
& \quad (\text{BlockTag } 3, []); \text{ Bignum } 8000000000000000])
\end{aligned}$$

As we know, the garbage collector moves heap elements and changes addresses. However, it will only transform heaps in a way that respects *gc_related*. We prove that *v_inv* properties can be transported from one heap to another if they are *gc_related*. In other words, execution of a garbage collector does not interfere with this data representation. Here $\text{addr_apply } f \text{ (Pointer } x \text{ } d) = \text{Pointer } (f \text{ } x) \text{ } d$.

$$\begin{aligned}
& \vdash gc_related \text{ } g \text{ heap}_1 \text{ heap}_2 \wedge (\forall ptr \text{ } u. x = \text{Pointer } ptr \text{ } u \Rightarrow ptr \in \text{domain } g) \wedge \\
& \quad v_inv \text{ conf } w \text{ (} x.f, \text{heap}_1) \Rightarrow \\
& \quad v_inv \text{ conf } w \text{ (addr_apply (apply } g) \text{ } x.g \circ f, \text{heap}_2)
\end{aligned}$$

In the formalisation, *v_inv* is used as part of *abs_ml_inv* (Fig. 4) which relates a list of values of type *v* and a reference mapping *refs* from *DATALANG* to a state representation at the level of the collector algorithm's verification proof. The state is a list of *roots*, a *heap*, and some other components. For the relation to be true, the roots and the heap have to be well-formed (*roots_ok* and *heap_ok* as mentioned previously); furthermore, the heap layout mandated by the generational collector must be true if a generational collector is used (*gc_kind_inv*), and *unused_space_inv* specifies that *sp* + *sp*₁ slots of unused space exists at heap location *a*. The *v_inv* relation is used inside of *bc_stack_ref_inv* which specifies the relationship between *stack* and *roots*: these lists have to be pairwise (*list_rel*) related by *v_inv*.

The invariant on the layout of the heap is specified in *gc_kind_inv* in Fig. 5. The length of the available space is always given by *sp* + *sp*₁, where *sp* is the space available before the GC trigger pointer, see Sect. 3.2. If a non-generational GC is used, then *sp*₁ must be zero indicating that the trigger is always at the end of the available space. For the generational collector, it must be possible to split the heap (*heap_split*) at the end of the available space so that all heap elements prior to this cut off are not references, and all heap elements after this pointer are references. Furthermore, each generation boundary *gens* must be well-formed (*gen_state_ok*). Here *gen_state_ok* states that there must not be any pointers from old data to new data, or more precisely, that every pointer must point to a location that is before the generation boundary or point into the references at the end of the heap.

At the time of writing, the algorithm-level formalisation is proved correct for a version which supports having several nested generations, but the word-level implementation of the algorithm has only been set up to work for at most one nursery generation, i.e. the setting where $\text{length } gens \leq 1$.

$$\begin{aligned}
& \text{abs_ml_inv } \text{conf } \text{stack refs } (\text{roots}, \text{heap}, \text{be}, a, \text{sp}, \text{sp}_1, \text{gens}) \text{ limit} \iff \\
& \quad \text{roots_ok } \text{roots } \text{heap} \wedge \text{heap_ok } \text{heap } \text{limit} \wedge \\
& \quad \text{gc_kind_inv } \text{conf } a \text{ sp } \text{sp}_1 \text{ gens } \text{heap} \wedge \\
& \quad \text{unused_space_inv } a \text{ (sp + sp}_1\text{) } \text{heap} \wedge \\
& \quad \text{bc_stack_ref_inv } \text{conf } \text{stack refs } (\text{roots}, \text{heap}, \text{be}) \\
& \text{unused_space_inv } \text{ptr } l \text{ heap} \iff \\
& \quad (l \neq 0 \Rightarrow \text{heap_lookup } \text{ptr } \text{heap} = \text{Some } (\text{Unused } (l - 1))) \wedge \\
& \quad \text{ptr} + l \leq \text{heap.length } \text{heap} \wedge \text{data_up_to } \text{ptr } \text{heap} \\
& \text{bc_stack_ref_inv } \text{conf } \text{stack refs } (\text{roots}, \text{heap}, \text{be}) \iff \\
& \quad \exists f. \\
& \quad \quad \text{injective } (\text{apply } f) \text{ (domain } f) \{ a \mid \text{isSomeDataElement } (\text{heap_lookup } a \text{ heap}) \} \wedge \\
& \quad \quad \text{domain } f \subseteq \text{domain refs} \wedge \text{list_rel } (\lambda v x. v_inv \text{ conf } v (x, f, \text{heap})) \text{ stack roots} \wedge \\
& \quad \quad \forall n. \text{reachable_refs } \text{stack refs } n \Rightarrow \text{bc_ref_inv } \text{conf } n \text{ refs } (f, \text{heap}, \text{be})
\end{aligned}$$

Fig. 4 Invariants in the compiler proof

$$\begin{aligned}
& \text{gc_kind_inv } c \text{ a sp } \text{sp}_1 \text{ gens } \text{heap} \iff \\
& \quad \text{case } c.\text{gc_kind} \text{ of} \\

\end{aligned}$$

Fig. 5 Invariants regarding the heap layout of the generational GC

4.2 Data Refinement Down to Concrete Memory

The relation provided by v_inv only gets us halfway down to WORDLANG's memory representation. In WORDLANG, values are of type `word_loc`, and memory is modelled as a function, $\alpha \text{ word} \rightarrow \alpha \text{ word_loc}$, and an address domain set.

We use separation-logic formulas to specify how abstract heaps, i.e. lists of `heap_elements`, are represented in memory. We define separating conjunction $*$, and use `fun2set` to turn a memory function m and its domain set dm into something we can write separation logic assertions about. The relevant definitions are:

$$\begin{aligned}
\text{split } s \ (u,v) &\iff u \cup v = s \wedge u \cap v = \emptyset \\
p * q &= (\lambda s. \exists u \ v. \text{split } s \ (u,v) \wedge p \ u \wedge q \ v) \\
a \mapsto x &= (\lambda s. s = \{ (a,x) \}) \\
\text{emp} &= (\lambda s. s = \emptyset) \\
\text{cond } c &= (\lambda s. s = \emptyset \wedge c) \\
\text{fun2set } (m, dm) &= \{ (a, m \ a) \mid a \in dm \}
\end{aligned}$$

Using this separation logic set up and a number of auxiliary functions, we define `word_heap a heap conf` to assert that a `heap_element` list `heap` is in memory, starting at address `a`. The definition of `word_heap`, which is partially shown in Fig. 6, uses `word_el` to assert that individual `heap_elements` are correctly represented. Here and throughout, `n2w` is a function which turns a natural number into the corresponding word modulo the word size. Numerals written with a `w`-suffix indicate that it is a word literal, i.e. `2w` is the same as `n2w 2`. Here `w << n` shifts word `w` by `n` bits left, and `(m - n) w` zeros bit `k` of word `w` if `k > m` or `k < n`.

Figure 7 shows an expansion of the `word_heap` assertion applied to our running example from the previous section.

4.3 Implementing the Garbage Collector

WORDLANG Implementation The garbage collector is used in the **WORDLANG** semantics as a function that the semantics of `Alloc` applies to memory when the allocation primitive runs out of memory. At this level, the garbage collector is essentially a function from a list of roots and a concrete memory to a new list of roots and concrete memory.

To implement the new garbage collector, we define a HOL function at the level of a concrete memory, and prove that it correctly mimics the operations performed by the algorithm-level implementation from Sect. 3.

In Fig. 8 we show the definition of `word_gen_gc_partial_move`, which is the refinement of `gen_gc_partial_move`. A side-by-side comparison with the latter (shown in Fig. 1) reveals that it's essentially the same function, recast in more concrete terms: for example, pattern matching on the constructor of the heap element is concretised by inspection of tag bits, and we must be explicit about converting between pointers (relative to the base address of the current heap) and (absolute) memory addresses. Note that it is still a specification. It is never executed: its only use is to define the semantics of **WORDLANG**'s garbage collection primitive.

To formally relate `word_gen_gc_partial_move` and `gen_gc_partial_move` we prove the following theorem, which states that the concrete memory is kept faithful to the algorithm's operations over the heaps. We prove similar theorems about the other components of the garbage collectors.

$$\begin{aligned}
&\vdash \text{gen_gc_partial_move } gc_conf \ s \ x = (x_1, s_1) \wedge \\
&\quad \text{word_gen_gc_partial_move } conf \ (\text{word_addr } conf \ x, \dots) = (w, \dots) \wedge \dots \wedge \\
&\quad (\text{word_heap } a \ s. \text{heap } conf * \text{word_heap } p \ s. \text{h2 } conf * \dots) \ (\text{fun2set } (m, dm)) \Rightarrow \\
&\quad w = \text{word_addr } conf \ x_1 \wedge \dots \wedge \\
&\quad (\text{word_heap } a \ s_1. \text{heap } conf * \text{word_heap } p_1 \ s_1. \text{h2 } conf * \dots) \ (\text{fun2set } (m_1, dm))
\end{aligned}$$

As a corollary of these theorems, we can lift the result from Sect. 3.4 that the generational garbage collector does not lose any live elements, to the same property about **WORDLANG**'s garbage collection primitive and the allocation function.

For the allocation primitive, we prove a key lemma shown in Fig. 9: if the state relation `state_rel` between **DATALANG** state `s` and **WORDLANG** state `t` holds, then running the allocation

```

word_heap a [] conf = emp
word_heap a (x::xs) conf =

word_addr conf (Pointer n w) = Word (get_addr conf n w)

get_addr conf n w = (n2w n << shift_length conf || get_lowerbits conf w)

get_lowerbits conf (Word w) = ((small_shift_length conf - 1 - 0) w || 1w)
get_lowerbits conf (Loc v3 v4) = 1w

```

Fig. 6 Some of the definitions for `word_heap`

routine on input k will either result in an abort with `NotEnoughSpace` (and an unchanged foreign-function interface state `ffi`) or in success (indicated by `res = None`) and space for k more slots in a new `WORDLANG` state `new_t` which is `state_rel`-related to a modified version of the original `DATALANG` state. Here `names` is the set of local variable names that need to be stored on the stack in case the garbage collector is called, i.e. it is the set of local variables that survive a call to the allocation routine.

With the help of such properties about the `WORDLANG`'s allocation routine, we can prove a compiler correctness theorem for the compiler phase from `DATALANG` to `WORDLANG`. Compiler correctness theorems are, in the context of the `CakeML` compiler [18], simulation relations as shown in Fig. 10.

```

```

Fig. 8 The WORDLANG shallow embedding of the move primitive for partial collection

Note that the compiler correctness theorem implies that the garbage collector must terminate on every cycle. This is because the theorem does not allow a terminating execution (e.g. one that terminates returning a value $\text{Rval } v$) to be simulated by a divergent execution. Here a divergent execution is one that results in Rtimeout_error for every value ck of the semantic clock. In the case of diverging source-language programs, the GC cannot diverge, since diverging executions must be simulated by diverging executions that exhibit the same observable events (i.e. the same FFI calls); hence if the GC diverged the STACKLANG program

$$\begin{aligned} &\vdash \text{state_rel } c \ l_1 \ l_2 \ s \ t \ [] \ \text{locs} \wedge \text{cut_env } \text{names } s.\text{locals} = \text{Some } \text{new_locals} \wedge \\ &\quad \text{alloc } k \ \text{names } t = (\text{res}, \text{new_t}) \Rightarrow \\ &\quad \text{res} = \text{Some NotEnoughSpace} \wedge \text{new_t}. \text{ffi} = t. \text{ffi} \vee \\ &\quad \text{res} = \text{None} \wedge \text{state_rel } c \ l_1 \ l_2 \ (s \text{ with } \langle \text{locals} := \text{new_locals}; \text{space} := k \rangle) \ \text{new_t} \ [] \ \text{locs} \end{aligned}$$

Fig. 9 Key lemma: the allocation primitive of WORDLANG either raises a NotEnoughSpace-exception or returns normally with a *new_t* state that relates to the original DATALANG state *s* updated to have *k* slots of space available

$$\begin{aligned} &\vdash \text{evaluate_data} (\text{Call None (Some start)} \ [] \ \text{None}, s) = (\text{res}, s_1) \wedge \\ &\quad \text{res} \neq \text{Some (Rerr (Rabort Rtype_error))} \wedge \text{state_rel_ext } x \ l_1 \ l_2 \ s \ t \Rightarrow \\ &\quad \exists ck \ t_1 \ \text{res}_1. \\ &\quad \text{evaluate_word} (\text{Call None (Some start)} \ [0] \ \text{None}, \text{inc_clock } ck \ t) = (\text{res}_1, t_1) \wedge \\ &\quad (\text{res}_1 = \text{Some NotEnoughSpace} \Rightarrow t_1. \text{ffi.io_events} \preceq s_1. \text{ffi.io_events}) \wedge \\ &\quad (\text{res}_1 \neq \text{Some NotEnoughSpace} \Rightarrow \\ &\quad \quad t_1. \text{ffi} = s_1. \text{ffi} \wedge \\ &\quad \quad \text{case } \text{res} \text{ of} \\ &\quad \quad \quad \text{None} \Rightarrow \text{res}_1 = \text{None} \\ &\quad \quad \quad \text{Some (Rval } v) \Rightarrow \exists w. \text{res}_1 = \text{Some (Result (Loc } l_1 \ l_2) \ w) \\ &\quad \quad \quad \text{Some (Rerr (Rraise } v')) \Rightarrow \exists v \ w. \text{res}_1 = \text{Some (Exception } v \ w) \\ &\quad \quad \quad \text{Some (Rerr (Rabort Rtype_error))} \Rightarrow \text{res}_1 = \text{Some TimeOut} \\ &\quad \quad \quad \text{Some (Rerr (Rabort Rtimeout_error))} \Rightarrow \text{res}_1 = \text{Some TimeOut} \\ &\quad \quad \quad \text{Some (Rerr (Rabort (Rffi_error } f)) \Rightarrow \text{res}_1 = \text{Some (FinalFFI } f)) \end{aligned}$$

Fig. 10 Correctness theorem relating DATALANG evaluation with WORDLANG evaluation. Here *state_rel_ext* relates DATALANG states *s* with WORDLANG states *t* and includes the requirements: (1) the code in state *t* is the compilation of the code in state *s*; (2) the GC is present in state *t*; and (3) all data from *s* is correctly represented in state *t*

would emit fewer FFI calls.³ For more details on this technique for treating divergence we refer to Owens et al. [15].

STACKLANG Implementation: As mentioned earlier, the WORDLANG garbage collection primitive needs to be implemented by a deep embedding that can be compiled with the rest of the code. This happens in the next intermediate language, STACKLANG, which uses the same data representation but concretises the stack and adds primitives for inspecting and manipulating it. These primitives are used to implement root scanning in the STACKLANG implementation of the GC.

The GC implementation is tedious: the STACKLANG programmer does not have the luxury of variables, and so must manually juggle data between registers and memory locations. To give the flavour, here is a pretty printed version of the STACKLANG code for a memory copying procedure. This code snippet copies *n* machine words from the memory location pointed to by register 2, to the memory location pointed to by register 3, where *n* is the contents of register 0. Here BYTES_IN_WORD is a target-specific constant specifying the number of bytes in a machine word: for 32-bit architectures it is 4 and 64-bit architectures it is 8. In HOL, the corresponding constant, *bytes_in_word*, is a constant whose value depends on its type, e.g. *bytes_in_word*:32 word = 4 and *bytes_in_word*:64 word = 8.

```
while (reg0 <> 0) {
  reg1 := mem[reg2];
  reg2 := reg2 + BYTES_IN_WORD;
  reg0 := reg0 - 1;
  mem[reg3] := reg1;
  reg3 := reg3 + BYTES_IN_WORD;
}
```

³ In principle, the theorem would allow for a GC that may diverge iff the source program diverges silently. This would be unproblematic since we would then simulate silent divergence with silent divergence.

The actual deep embedding as `STACKLANG` code is the following:

```
memcpy_code =
  While NotEqual 0 (Imm 0w)
    (Seq (Inst (Mem Load 1 (Addr 2 0w)))
      (Seq (Inst (Arith (Binop Add 2 2 (Imm bytes_in_word))))
        (Seq (Inst (Arith (Binop Sub 0 0 (Imm 1w))))
          (Seq (Inst (Mem Store 1 (Addr 3 0w)))
            (Inst (Arith (Binop Add 3 3 (Imm bytes_in_word))))))))))
```

Here $0w$ denotes the machine word where all bits are 0, and $1w$ the machine word where all bits are 0 save for the LSB.

We prove that according to `STACKLANG`'s big-step semantics, evaluating this program computes the same function and has the same effect on memory as the corresponding shallow embedding `memcpy` does:

$$\begin{aligned} \vdash \text{memcpy } (n2w \ n) \ a \ b \ m \ dm &= (b_1, m_1, T) \wedge n < \text{dimword } (: \alpha) \wedge s.\text{memory} = m \wedge \\ s.\text{mdomain} &= dm \wedge \text{get_var } 0 \ s = \text{Some } (\text{Word } (n2w \ n)) \wedge 1 \in \text{domain } s.\text{regs} \wedge \\ \text{get_var } 2 \ s &= \text{Some } (\text{Word } a) \wedge \text{get_var } 3 \ s = \text{Some } (\text{Word } b) \Rightarrow \\ \exists r_1. & \\ \text{evaluate } (\text{memcpy_code}, s \text{ with clock } := s.\text{clock} + n) &= \\ (\text{None}, & \\ s \text{ with} & \\ \Downarrow \text{memory } := m_1; & \\ \text{regs } := & \\ s.\text{regs} \uparrow\uparrow & \\ [(0, \text{Word } 0w); (1, r_1); (2, \text{Word } (a + n2w \ n * \text{bytes_in_word}))]; & \\ (3, \text{Word } b_1)] \Downarrow & \end{aligned}$$

Here $\uparrow\uparrow$ updates a finite map with the key-value pairs in the RHS. We prove similar theorems about all the constituent parts of the GC implementation, allowing us to lift the result that the `WORDLANG` garbage collection primitive does not lose live elements to the same result about its `STACKLANG` implementation.

Root scanning is made explicit and implemented in the `STACKLANG` implementation. The root scanning code has to find and process all current roots in the program stack. This is made tedious because not all slots in the stack contain active data or data that is relevant to the GC. Each stack frame is marked with an identifier which is a pointer into a separate data structure where the GC can at runtime find a compact representation of a description of the structure of the stack frame. Verification of the root scanning code is not particularly difficult, but the proofs are long due to the low-level nature of the compact stack frame descriptions, which is described in previous work [18].

The `STACKLANG` implementation of the GC is injected into the program to be compiled as part of the `STACKLANG` phases of the compiler. At this point all uses of the allocation primitive have been replaced by calls to the GC implementation. From this point onwards, the code for the GC is just another part of the program to be compiled, and there is no need for the remaining passes to even be aware of whether the code contains a garbage collector.

5 Timing the GC

In this section, we evaluate how the performance of our new generational garbage collector compares to CakeML's pre-existing copying collector on a number of benchmarks. We have several objectives here. We would like to discover whether the new generational collector is performant enough to be a useful addition to the CakeML ecosystem, and if so, to give users some hints about what kind of programs our collector might be useful for. Moreover, we are interested in the performance penalty that maintaining our heap layout incurs on non-generational copying collection.

Benchmark Suite

Our first seven benchmarks are taken from the MLton repository.⁴ They exclude benchmarks that use features currently unsupported by CakeML, and features that are treated in substantially different ways by MLton and CakeML (records, system calls, machine words, floating point numbers). Moreover, we exclude benchmarks whose memory footprint is too small to trigger the copying collector. For the remaining benchmarks, we modified minor details like syntax and currying to make the benchmarks compatible with CakeML's parser and basis library.

The remaining benchmarks repeatedly create short-lived binary trees of various depths, simulating programs that require different amounts of short-lived live data in addition to a fixed amount of long-lived data allocated at the start of the program. The depths considered go from 5 (157 machine words in memory) to 16 (327,677 machine words in memory). We would expect the generational collector to perform better with smaller trees that fit comfortably in a generation, but worse on bigger trees.

Setup We compiled each benchmark program with the heap size set to 10 MB—the small size makes sure we trigger plenty of collection cycles—and with a variety of different garbage collection settings:

1. (*copying*): Copying GC
2. (*no-gen*): Generational GC, with generation size > heap size (hence partial collection never triggers).
3. (*small-gen*): Generational GC, with 100,000 word generation size
4. (*large-gen*): Generational GC, with 200,000 word generation size

All benchmarks were run on a 4 GHz Intel(R) Core(tm) i7-6700K CPU and 32 GB of memory, running Debian 4.9.82-1. Presented results are the average over 100 runs. In order to allow us to distinguish GC time from other time, we run the compiler in a debug mode which injects snippets of timing code at GC entry and exit.

Results Table 1 shows our benchmark results for the MLton benchmarks. We see that the relative performance of our collectors varies wildly: from *imp-for* where the generational GC performs worse by two orders of magnitude, to *smith-normal-form* where the generational GC performs approximately 4 times better.

The benchmark *imp-for* consists of 7 nested for-style loops that allocate around 100 million references in total, and uses very little immutable data. That a program with such an allocation pattern does not benefit from our generational garbage collection scheme is hardly surprising: when most data is mutable, running collection cycles on only the immutable data is a waste of time. The other example where generational collection underperforms is *pidigits*, which is based on an encoding of lazy lists as a function for producing the tail;

⁴ <https://github.com/MLton/mlton/tree/master/benchmark>.

Table 1 MLton benchmark results, measured as total garbage collection time in milliseconds with different collector settings (and as percentage of the benchmark's total run-time)

	<i>copying</i>	<i>no-gen</i>	<i>small-gen</i>	<i>large-gen</i>
merge	7520 (63%)	6830 (61%)	11,300 (74%)	6700 (62%)

Total garbage collection time in milliseconds with different collector settings (and as percentage of the benchmark's total run-time). Best-performing collector on each benchmark indicated in boldface

more research is needed to determine why the generational GC would be bad for such an application.

The smith-normal-form has several features that seem a good fit for generational collection. It uses references, albeit more sparingly than `imp-for`: it represents 35×35 matrices as `int` arrays, so collecting the references themselves would be of relatively little use. The fact that the references point at integers that change frequently means high turnover of data and a small footprint of live data at all times. Hence partial cycles are likely to be quick (not much more to see after following each reference to an integer) and free up plenty of space (1225 integers is very little live data).

The difference between the columns *copying* and *no-gen* shows the overhead incurred by maintaining our heap layout, which turns out to be negligible. The difference between *small-gen* and *large-gen* suggest that all else being equal, larger generation sizes are preferable.

Table 2 shows our results for the tree allocation benchmarks. We see that the performance profile of our generational collector vs the copying collector is as expected: when the amount of live non-persistent data at any one time is much smaller than the generation size, the generational collector outperforms the copying collector by two orders of magnitude. The collection time for the generational collector grows linearly in the size of the non-persistent live memory (i.e. exponentially in the tree depth), until it starts performing worse than the copying collector when the trees no longer fit comfortably in a generation. Meanwhile, the performance profile of copying collection is more flat. At depth 16, both collectors start

exhibiting degenerate performance as the size of the trees approaches the heap size. Trees of depth 17 are too big to fit in the heap regardless of which collection scheme is used.

In conclusion, we find that the generational collector is indeed a useful addition to the CakeML ecosystem that can improve the performance of programs where most new data has small live ranges. Of course, neither the generational nor the copying collector is a clear winner for all use cases, and the optimal choice of collector will depend heavily on the allocation pattern of the user program under consideration. We encourage performance-conscious compiler users to perform their own experiments to determine which settings fit their programs. However, it is worth stressing that when program responsiveness matters, the generational GC is often preferable when the performance difference is small, because the same total GC time is spread out over many shorter collection cycles.

6 Discussion of Related Work

Anand et al. [1] reports that the CertiCoq project has a “high-performance generational garbage collector” and a project is underway to verify this using Verifiable C in Coq. Their setting is simpler than ours in that their programs are purely functional, i.e. they can avoid dealing with the added complexity of mutable state. The text also suggests that their garbage collector is specific to a fixed data representation. In contrast, the CakeML compiler allows a highly configurable data representation, which is likely to become more configurable in the future. The CakeML compiler generates a new garbage collector implementation for each configuration of the data representation.

CakeML’s original non-generational copying collector has its origin in the verified collector described in Myreen [12]. The same verified algorithm was used for a verified Lisp implementation [13] which in turn was used underneath the proved-to-be-sound Milawa prover [2]. These Lisp and ML implementations are amongst the very few systems that use verified garbage collectors as mere components of much larger verified implementations. Verve OS [19] and Ironclad Apps [9] are verified stacks that use verified garbage collectors internally.

Numerous abstract garbage collector algorithms have been mechanically verified before. However, most of these only verify the correctness at the algorithm-level implementation and only consider mark-and-sweep algorithms. Noteworthy exceptions include Hawblitzel and Petrank [10], McCreight [11], and Gammie et al. [5].

Hawblitzel and Petrank [10] show that performant verified x86 code for simple mark-and-sweep and Cheney copying collectors can be developed using the Boogie verification condition generator and the Z3 automated theorem prover. Their method requires the user to write extensive annotations in the code to be verified. These annotations are automatically checked by the tools. Their collector implementations are realistic enough to show good results on off-the-shelf C# benchmarks. This required them to support complicated features such as interior pointers, which CakeML’s collector does not support. We decided to not support interior pointers in CakeML because they are not strictly needed and they would make the inner loop of the collector a bit more complicated, which would probably cause the inner loop to run a little slower.

McCreight [11] verifies copying and incremental collectors implemented in MIPS-like assembly. The development is done in Coq, and casts his verification efforts in a common framework based on ADTs that all the collectors refine.

Gammie et al. [5] verify a detailed model of a state-of-the-art concurrent mark-and-sweep collector in Isabelle/HOL, with respect to an x86-TSO memory model. A related effort by Zakowski et al. [20] uses Coq to verify a concurrent mark-and-sweep collector expressed in a purpose-built compiler intermediate representation rather than the pseudocode of Gammie et al., although Zakowski et al. verifies theirs with respect to an interleaving semantics.

Pavlovic et al. [16] focus on an earlier step, namely the synthesis of concurrent collection algorithms from abstract specifications. The algorithms thus obtained are at a similar level of abstraction to the algorithm-level implementation that we start from. The specifications are cast in lattice-theoretic terms, so e.g. computing the set of live nodes is fixpoint iteration over a function that follows pointers from an element. A main contribution is an adaptation of the classic fixpoint theorems to a setting where the monotone function under consideration may change, which can be thought of as representing interference by mutators.

This paper started by listing incremental, generational, and concurrent as variations on the basic garbage collection algorithms. There have been prior verifications of incremental algorithms (e.g. [8,11,14,17]) and concurrent ones (e.g. [3,5,6,16]), but we believe that this paper is the first to report on a successful verification of a generational garbage collector.

7 Summary

This paper verifies a generational copying garbage collector and integrates it into the verified CakeML compiler. The algorithm-level part of our proof is structured to follow the usual informal argument for a generational collector's correctness: a partial collection is the same as running a full collection on part of the heap if pointers to old data are treated as non-pointers. To the best of our knowledge, this paper is the first to report on a completed formal verification of a generational garbage collector.
