**ABSTRACT:** The Large and Small Magellanic Clouds (LMC and SMC), gas-rich dwarf companions of the Milky Way, are the nearest laboratories for detailed studies on the formation and survival of complex organic molecules (COMs) under metal-poor conditions. To date, only methanol, methyl formate, and dimethyl ether have been detected in these galaxies—all three toward two hot cores in the N113 star-forming region in the LMC, the only extragalactic sources exhibiting complex hot-core chemistry. We describe a small and diverse sample of the LMC and SMC sources associated with COMs or hot-core chemistry, and compare the observations to theoretical model predictions. Theoretical models accounting for the physical conditions and metallicity of hot molecular cores in the Magellanic Clouds have been able to broadly account for the existing observations, but they fail to reproduce the

dimethyl ether abundance by more than an order of magnitude. We discuss future prospects for research in the field of complex chemistry in the lowmetallicity environment. The detection of COMs in the Magellanic Clouds has important implications for astrobiology. The metallicity of the Magellanic Clouds is similar to that of galaxies in the earlier epochs of the universe; thus, the presence of COMs in the LMC and SMC indicates that a similar prebiotic chemistry leading to the emergence of life, as it happened on Earth, is possible in low-metallicity systems in the earlier universe.

**KEYWORDS:** Magellanic Clouds, star formation, astrochemistry, complex organic molecules, molecular abundances

# 1. INTRODUCTION

An important issue for astrochemistry is to understand how the organic chemistry in low-metallicity environments (i.e., with low abundances of elements heavier than hydrogen or helium), relevant for star formation at earlier epochs of cosmic evolution, differs from that in the Galaxy. Large aromatic organic molecules Special Issue: Complex Organic Molecules (COMs) in Star-Forming Regions

Received:March 19, 2019Revised:August 26, 2019Accepted:August 27, 2019Published:August 27, 2019

such as polycyclic aromatic hydrocarbons (PAHs) are detected in high-redshift galaxies, but the formation efficiency of smaller complex organic molecules (COMs) has been unknown. A quantitative determination of the organic chemistry in highredshift galaxies with different star formation histories, and lower abundances of the important biogenic elements (C, O, N, S, P), can shed light on the inventory of COMs available to planetary systems and their potential for harboring life (e.g., ref 1). The nearest laboratories for detailed studies of star formation under metal-poor conditions are the Large and Small Magellanic Clouds (LMC and SMC).

The LMC and SMC are gas-rich dwarf companions of the Milky Way located at a distance of  $(50.0 \pm 1.1)$  kpc (ref 2) and  $(62.1 \pm 2.0)$  kpc (ref 3), respectively. They are the nearest starforming galaxies with metallicities Z (the mass fractions of all the chemical elements other than hydrogen and helium) lower than that in the solar neighborhood ( $Z_{\odot} = 0.0134$ ):<sup>4</sup>  $Z_{LMC} \approx 0.3-0.5$  $Z_{\odot}$  and  $Z_{\rm SMC} \approx 0.2 Z_{\odot}^{.5,6}$  Apart from the lower elemental abundances of gaseous C, O, and N atoms (e.g., ref 7), low metallicity leads to less shielding (due to the lower dust abundance; e.g., refs 8 and 9), greater penetration of UV photons into the interstellar medium, and consequently warmer dust grains (e.g., refs 10 and 11). The interstellar ultraviolet radiation field in the LMC and SMC is 10-100 higher than typical Galactic values (e.g., ref 12). Gamma-ray observations indicate that the cosmic-ray density in the LMC and SMC is respectively ~25% and ~15% of that measured in the solar neighborhood (refs 13 and 14). All these low-metallicity effects may have direct consequences on the formation efficiency and survival of COMs, although their relative importance remains unclear.

The range of metallicities observed in the Magellanic Clouds is similar to that in galaxies at redshift  $z \approx 1.5-2$ , i.e., at the peak of the star formation in the universe (between  $\sim 2.8$  and  $\sim 3.5$ billion years after the Big Bang; e.g., ref 15), making them ideal templates for studying star formation and complex chemistry in low-metallicity systems in an earlier universe where direct measurements of resolved stellar populations are not possible. Only very recently have gaseous COMs (methanol: CH<sub>3</sub>OH, methyl formate: HCOOCH<sub>3</sub>, dimethyl ether: CH<sub>3</sub>OCH<sub>3</sub>) been detected in the LMC<sup>16-18</sup> and in the SMC,<sup>19</sup> using the Atacama Large Millimeter/sub-millimeter Array (ALMA). These observations showed that interstellar COMs can form in the lowmetallicity environments, probably in the hot molecular cores and corinos associated with massive and low- to intermediatemass protostars, respectively. COMs had previously been detected outside the Milky Way, but in galaxies with metallicities comparable to or higher than solar values (see ref 20 and references therein).

In this Review, we summarize the current state of knowledge concerning the organic chemistry in the Magellanic Clouds.

### 2. MOLECULAR LINE INVENTORIES IN STAR-FORMING REGIONS OF THE MAGELLANIC CLOUDS

The proximity of the LMC/SMC enables both detailed studies of individual star-forming regions and statistical studies of molecular clouds or stellar populations on galactic scales. The systematic studies of molecular clouds in the Magellanic Clouds started with the <sup>12</sup>CO J = 1-0 survey of the LMC (central 6° × 6°)<sup>22</sup> and the SMC (2° × 2°),<sup>23</sup> with a resolution of 8.'8 (the Columbia 1.2-m Millimeter-WaveTelescope), followed by a higher resolution (2.'6) survey of both galaxies with the

NANTEN 4-m telescope (e.g., refs 24 and 25). The more sensitive NANTEN survey that identified 272 molecular clouds in the LMC was published in ref 26. The most luminous CO clouds from this survey were observed with 45" resolution using the Australia Telescope National Facility (ATNF) Mopra 22-m Telescope (the MAGMA survey).<sup>27</sup>

The molecular gas in the Magellanic Clouds was also investigated using the CO data from the ESO SEST (Swedish/ESO Submillimeter Telescope) Key-Program (CO J = 1–0 and 2–1 lines with 50" and 25" half-power beam widths, HPBWs)<sup>28</sup> toward 92 and 42 positions in the LMC and SMC, respectively, mostly coincident with IRAS sources; the results were reported in multiple papers, including detailed studies of major star-forming giant molecular clouds (GMCs) and less active cloud complexes in the LMC and small molecular cloud complexes in the SMC (see ref 29 and references therein). Many other CO studies of individual star-forming regions with SEST in both the LMC and SMC followed (e.g., LMC regions N159W, N113, N44BC, and N214DE).<sup>30</sup>

The first unbiased spectral line survey of an individual starforming region in the LMC was reported in ref 31, using SEST and centered on the N159W molecular peak in N159—the brightest NANTEN GMC with H II regions. The observations covered a 215–245 GHz frequency range in several bands and selected bright lines at lower frequencies (~100 GHz; HPBW ~23" at 220 GHz and 50" at 100 GHz). No COM transitions covered by these observations (e.g., propyne: CH<sub>3</sub>CCH J = 5–4 and J = 6–5 and CH<sub>3</sub>OCH<sub>3</sub>J = 6–5 lines) were detected. In ref 31, it was reported that fractional abundances with respect to H<sub>2</sub> for molecules detected in N159W (<sup>13</sup>CO, C<sup>18</sup>O, CS, SO, HCO<sup>+</sup>, HCN, HNC, CN, and H<sub>2</sub>CO (formaldehyde)) are typically a factor of 10 lower than those observed in the Galaxy.

The multi-region, multi-line SEST 3 mm (85–115 GHz) survey described in ref 32 focused on one SMC (LIRS 36 or N12) and four LMC (N113, N44BC, N159HW, and N214DE) molecular cloud cores. They detected the C<sub>2</sub>H, HCN, HCO<sup>+</sup>, HNC, CS, <sup>13</sup>CO, CN, and <sup>12</sup>CO transitions, but the CH<sub>3</sub>OH J = 2–1 line at ~96.74 GHz covered by their observations was not detected toward any of the regions. The follow-up study on N12 in the SMC included the 2, 1.3, and 0.85 mm SEST bands, but also failed to detect CH<sub>3</sub>OH or other COMs.<sup>33</sup>

The first detection of a COM in the Magellanic Clouds was reported in ref 16 for a SEST 0.85, 1.3, 2, and 3 mm survey of the SMC LIRS 49 (or N27) and LMC 30 Dor-10, 30 Dor-27, N159W, N159S, and N160 regions, covering a range of metallicities and UV radiation strengths. N159W was the only region where CH<sub>3</sub>OH was detected: I = 2-1 and two 3-2 lines at ~96.7 and ~145.1 GHz, respectively (see Table 1). The observations in ref 16 covered the J = 6-5 and J = 8-7 lines of CH<sub>3</sub>CCH, but only marginal (~2.5 $\sigma$ ) detections are reported toward one region: N159W. The CH<sub>3</sub>OH fractional abundance with respect to H<sub>2</sub> was estimated to be  $4.3 \times 10^{-10}$  in N159W. The authors indicated that the derived physical and chemical quantities are averages over spatial scales probed by their observations (10–15 pc in the 3 mm, and 5–10 pc in the 2/1.3mm bands). Overall, the molecular abundances in N159W where  $CH_3OH$  was detected are typically 5–20 times lower than those measured in the Galactic molecular clouds, assuming that hydrogen is mainly in molecular form within the clouds. It was concluded that reduced abundances are likely to be a combined effect of lower abundances of carbon and oxygen and higher photodissociation rates of molecules, both due to the lower metallicity in the LMC.

region	species	transition	frequency (GHz)	$E_{\rm U}$ (K)	ref
N159W	CH <sub>3</sub> OH, $v_t = 0^c$	2 <sub>-1,2</sub> -1 <sub>-1,1</sub> E	96.739362	12.54	16
		2 <sub>0,2</sub> -1 <sub>0,1</sub> A <sup>+</sup>	96.741375	6.97	16
		$2_{0,2} - 1_{0,1} E$	96.744550	20.09	16
		2 <sub>1,1</sub> -1 <sub>1,0</sub> E	96.755511	28.01	16

Table 1.	CH <sub>2</sub> OH	Transitions	Detected in	1 the LMC i	in Single-Dish	Observations <sup><i>a</i>,<i>b</i></sup>
					<u>a</u>	

"All the observations were conducted with SEST. The SEST's half-power beam sizes are 61''-54'' and 47''-24'' in frequency ranges of 85–98 and 109–219 GHz, respectively.<sup>17</sup> <sup>b</sup>The table uses the Cologne Database for Molecular Spectroscopy (CDMS) notation from the National Radio Astronomy Observatory (NRAO) Spectral Line Catalog (Splatalogue). For CH<sub>3</sub>OH ( $NK_aK_cp\nu$ ), a sign value of  $K_a$  is used to differentiate  $E_1(+)$  and  $E_2(-)$  states (both belong to the same *E* symmetry species). <sup>c</sup>The four transitions at ~96.7 GHz are blended.

An extensive spectral line study on N113, previously observed in ref 32 at 3 mm (see above), provided new detections of CH<sub>3</sub>OH.<sup>17</sup> Their SEST observations covered the 0.85, 1.3, 2, and 3 mm bands. The rich spectral line inventory included two J = 2–1 and two J = 3–2 lines of CH<sub>3</sub>OH (see Table 1). The CH<sub>3</sub>OH abundance with respect to H<sub>2</sub> was estimated to be ~5 ×  $10^{-10}$ , similar to that observed in N159W in ref 16, and an order of magnitude lower than that observed in the Galaxy.

N113 and N159W remain the best-studied regions in the LMC in terms of chemical inventory. The initial single-dish surveys were followed by interferometric observations with the Australia Telescope Compact Array (ATCA) with 4''-6'' angular resolutions (N113 only, ref 34, and N113, N159, N105, and N44, ref 35) that focused on dense gas tracers such as HCO<sup>+</sup> and HCN. The authors of ref 36 searched for NH<sub>3</sub> (1, 1) and (2, 2) in seven star-forming regions in the LMC (N113, N159W, N159S, 30 Dor 10, N44 BC, N105 A, and N83 A) with ATCA (HPBW  $\approx 9''-17''$ ) and only detected it toward N159W with an abundance of  $\sim 4 \times 10^{-10}$  with respect to H<sub>2</sub>: 1.5–5 orders of magnitude lower than observed in Galactic star-forming regions.

The most recent multi-region, multi-line single-dish survey, described in ref 37, used the Mopra 22-m telescope's 3 mm band (HPBW  $\approx 38''$  at 90 GHz and 30'' at 115 GHz). The sample included seven H II regions: NQC2, CO Peak 1, N79, N44C, N11B, N113, and N159W. That work confirmed lower molecular abundances in the LMC star-forming regions. Those observations failed to detect CH<sub>3</sub>OH and other COMs.

The results of the single-dish molecular line surveys of individual H II regions in the LMC and SMC indicate a deficiency of CH<sub>3</sub>OH in these low-metallicity galaxies. This deficiency is also supported by the low detection rate of CH<sub>3</sub>OH masers in the Magellanic Clouds. Ref 38 described a complete systematic survey for 6668 MHz CH<sub>3</sub>OH and 6035 MHz excited-state OH masers in both the LMC and SMC using the Methanol Multibeam (MMB) survey receiver on the 64-m Parkes telescope (HPBW  $\approx$  3.'3), supplemented by higher sensitivity targeted observations of known star-forming regions. The survey resulted in a detection of only one maser of each kind, increasing the number of known 6668 MHz CH<sub>3</sub>OH masers in the LMC to four.<sup>39–41</sup> Ref 42 later reported detection of a single 12.2 GHz CH<sub>3</sub>OH maser in the LMC. To date, no CH<sub>3</sub>OH masers have been detected in the SMC. The authors of ref 38 estimated that CH<sub>3</sub>OH masers in the LMC are underabundant by a factor of ~45 (or ~4–5 after correcting for differences in the star formation rates between the galaxies) and interstellar OH and  $H_2O$  masers by a factor of ~10 compared to the Galaxy.

The Spitzer Space Telescope (referred to herein simply as Spitzer)<sup>43</sup> and Herschel Space Observatory (referred to as Herschel)<sup>44</sup> enabled studies of young stellar object (YSO) populations in the LMC and SMC, both galaxy-wide and in individual star-forming regions. Using the data from the Spitzer "Surveying the Agents of Galaxy Evolution" (SAGE)<sup>45</sup> and "Surveying the Agents of Galaxy Evolution in the Tidally Stripped, Low Metallicity Small Magellanic Cloud" (SAGE-SMC),<sup>46</sup> thousands of YSO candidates were identified in the Magellanic Clouds, dramatically increasing the number of previously known YSOs (from 20/1 in the LMC/SMC; e.g., refs 47-52). YSOs detected by Spitzer include mostly Stage I (protostars with accreting envelopes and disks) and also Stage II (disk-only) YSOs; the youngest Stage 0/I YSOs (protostars in the main accretion stage) were identified with Herschel using the data from the "HERschel Inventory of The Agents of Galaxy Evolution" (HERITAGE)<sup>21</sup> survey (e.g., refs 53 and 54). The AKARI "Large-area Survey of the Large Magellanic Cloud" (LSLMC) also carried out near- to mid-infrared photometric survey and near-infrared slitless spectroscopic survey toward the LMC, whose data sets also are used to search for YSOs in the LMC.<sup>55–57</sup> On a galaxy-wide scale, YSO lists can be utilized to determine a star formation rate in each galaxy. On scales of individual star-forming clouds, YSO catalogs can also be used to study star formation rate, star formation efficiency, and the evolutionary stage of the GMCs and to provide targets for follow-up detailed observations.

Spectroscopic follow-up observations of *Spitzer*, *Herschel*, and *AKARI* YSO candidates in the LMC and SMC revealed chemical differences in the YSO envelopes between these galaxies and compared to Galactic YSOs, which can be explained as a consequence of differences in metallicity (see section 3).

# 3. NEAR- TO MID-INFRARED SPECTROSCOPY: MORE EVIDENCE FOR CHEMICAL DIFFERENCES BETWEEN THE LMC, SMC, AND THE MILKY WAY

The mid-infrared studies on the LMC YSOs with *Spitzer* Infrared Spectrograph (IRS)<sup>11,58–60</sup> and near-infrared studies with the AKARI satellite<sup>61,62</sup> and ground-based instrumentation<sup>11,59</sup> found differences in ice chemistry between the LMC

and the Galaxy. In cold molecular clouds, layers of ice form on the surface of dust grains. The main constituent of ice in envelopes of YSOs is  $H_2O$ , mixed primarily with CO and CO<sub>2</sub>.<sup>63</sup> Since the  $H_2O$  ice abundances (~10<sup>-4</sup>; e.g., refs 64 and 65) exceed by a few orders of magnitude the gas-phase abundances, understanding gas-grain processes is crucial to fully understand the chemistry in the YSO envelopes.

In the LMC and by comparison to Galactic samples,  $CO_2$  ice column densities are enhanced with respect to  $H_2O$  ice, <sup>58,60,62</sup> while relative CO-to-CO<sub>2</sub> abundances are unchanged.<sup>11</sup> The authors of ref 11 proposed the scenario where the high CO<sub>2</sub>/  $H_2O$  ratio is due to the low abundance of  $H_2O$  in the LMC. If there is a difference in the optical extinction  $A_V$  threshold for  $H_2O$  and CO<sub>2</sub> ices (as the observations suggest), there could be an envelope of less shielded material that shows  $H_2O$  ice but no  $CO_2$  ice. The strong interstellar radiation in the LMC penetrates deeper into the YSO envelopes as compared with Galactic YSOs, possibly destroying  $H_2O$  ice in less-shielded outer layers without affecting CO<sub>2</sub> and  $H_2O$  ice mixtures that exist deeper in the envelope.

In their Very Large Telescope (VLT)'s "Infrared Spectrometer And Array Camera" (ISAAC) near-infrared spectroscopic observations, the authors of ref 66 marginally detected CH<sub>3</sub>OH ice absorption band toward two embedded massive YSOs in the LMC with the abundances suggesting that solid CH<sub>3</sub>OH is less abundant for high-mass YSOs in the LMC than those in the Galaxy. They proposed a model which explains both the low abundance of CH<sub>3</sub>OH and the higher abundance of solid CO<sub>2</sub> found in previous studies. In this "warm ice chemistry" model, the grain surface reactions at a relatively high temperature ( $T \gtrsim$ 20 K) are responsible for the observed characteristics of ice chemical composition in the LMC. The high dust temperature in the low-metallicity environment caused by the strong interstellar radiation field leads to inefficient H atom sticking and CO hydrogenation to CH<sub>3</sub>OH on grain surfaces. At the same time, the production of  $CO_2$  is enhanced as a result of the increased mobility of parent species (CO and OH; see section 5.2.1 for a discussion on theoretical models).

The Spitzer/IRS spectroscopy also revealed several COMs in the circumstellar environment of SMP LMC 11 (or LHA 120-N78), an object in the LMC classified as a carbon-rich planetary nebula (PN) in the optical, but with infrared properties consistent with it being in the transition from the postasymptotic giant branch (AGB) to the PN stage (e.g., ref 67 and references therein). The authors of ref 67 identified the diacetylene  $(C_4H_2)$ , ethylene  $(C_2H_4)$ , triacetylene  $(C_6H_2)$ , benzene  $(C_6H_6)$ , and possibly methylacetylene  $(CH_3C_2H;$ commonly known as propyne which is found also in Titan's atmosphere) absorption bands in the Spitzer/IRS spectrum of SMP LMC 11. C<sub>6</sub>H<sub>6</sub> is a simplest building block of PAHs, which are abundant and ubiquitous in the interstellar medium (e.g., ref 68). In the subsequent analysis and modeling of the same Spitzer/IRS spectrum, the authors of ref 69 questioned the detection of  $C_6H_{21}$  but confirmed the detection of  $CH_3C_2H$ . SMP LMC 11 shows a peculiar chemistry, not typical for PN or post-AGB objects in general; e.g., it is one of only two evolved stars in which hydrocarbons up to benzene in absorption are detected (e.g., refs 69-71).

# 4. THE QUEST FOR DETECTING COMs IN THE MAGELLANIC CLOUDS WITH ALMA

The detection of CH<sub>3</sub>OH and more complex molecules in the Magellanic Clouds has been accelerated by the advent of ALMA.

Review

**Figure 1.** Three-color composite mosaics of the LMC (*top*) and SMC (*bottom*), combining the *Herschel*/HERITAGE 250  $\mu$ m (red), 160  $\mu$ m (green), and 100  $\mu$ m (blue) images.<sup>21</sup> Star-forming regions harboring sources with the detection of COMs (N113 and N159 in the LMC and N78 in the SMC; see Table 2) are indicated with yellow arrows and labeled. The location of the star-forming region N144 hosting ST11, a hot core without COMs, is indicated in white. North is up and east to the left.

ALMA provides high spatial resolution and sensitivity, which enabled studies in the LMC/SMC that in the pre-ALMA era were only possible in our Galaxy. The wide frequency coverage of ALMA observations (up to four ~2 GHz spectral windows in the sub-mm/mm wavelength range) allows for simultaneous observations of multiple molecular species and enables serendipitous discoveries.

**4.1.** Hot Core without COMs: LMC ST11. ST11 is a highmass YSO (~5 × 10<sup>5</sup> L<sub>☉</sub>, *Spitzer* YSO 052646.61-684847.2,<sup>47,48,54,62,72</sup> or IRAS 05270-6851) located in the N144 star-forming region in the LMC (Figures 1 and 2). In the pre-ALMA era, the spectral properties of the source were well studied with mid-infrared and near-infrared spectroscopy, which have detected absorption bands due to H<sub>2</sub>O ice, CO<sub>2</sub> ice, and silicate dust, as well as emission due to PAHs and hydrogen recombination lines.<sup>62,72</sup>

The high-resolution ( $\sim 0.75$  or  $\sim 0.12$  pc) sub-millimeter ( $\sim 0.86$  mm) observations toward ST11 with ALMA revealed the presence of a hot molecular core associated with the

**Figure 2.** *Left:* Three-color mosaic combining the InfraRed Survey Facility (IRSF)  $K_s$  (red), H (green), and J (blue)<sup>74</sup> images for the LMC source ST11: the source with a hot-core chemistry, but no COMs detection.<sup>73</sup> *Right:* A three-color mosaic combining the *Spitzer*/SAGE 8.0  $\mu$ m (red) and 4.5  $\mu$ m (green) images<sup>45</sup> and the MCELS H $\alpha$  (blue) image.<sup>75</sup> The ALMA 840  $\mu$ m continuum contours are overlaid on the image in the left panel; the contour levels are (3, 6, 20, 40) × 0.94 mJy beam<sup>-1</sup>, the 840  $\mu$ m image rms noise level. The ALMA beam size is 0." 5 × 0." 5. The red × symbol in the left panel indicates the position of the *Spitzer* YSO: the bright source in the mosaic shown in the right panel.

source.<sup>73</sup> According to the rotational diagram analysis of multiple  ${}^{32}SO_2$  and  ${}^{34}SO_2$  lines, the gas temperature of the hot-core region is estimated to be  $\sim 100-200$  K. The total gas density of the source is estimated to be higher than  $2 \times 10^6$  cm<sup>-3</sup> based on the analysis of the sub-millimeter dust continuum. Emission lines of CO, C<sup>17</sup>O, HCO<sup>+</sup>, H<sup>13</sup>CO<sup>+</sup>, H<sub>2</sub>CO, NO, H<sub>2</sub>CS,  ${}^{33}SO_2$ , and SiO are also detected from the compact region associated with the source. High-velocity components are detected in the line profile of CO (3–2), which suggests the presence of molecular outflow in this source.

CH<sub>3</sub>OH and larger COMs are not detected toward ST11, despite the high gas temperature that is sufficient for the ice sublimation and despite the detection of H<sub>2</sub>CO, a small organic molecule. The estimated upper limit on the CH<sub>3</sub>OH gas fractional abundance of  $8 \times 10^{-10}$  is significantly lower than those of Galactic hot cores by a few orders of magnitude<sup>73</sup> (see Table 3). The authors of ref 73 hypothesized that the inhibited formation of CH<sub>3</sub>OH on the dust surface before the hot-core stage could be responsible for this deficiency. They also estimated upper limits on fractional abundances with respect to H<sub>2</sub> for (CH<sub>3</sub>OCH<sub>3</sub>, HCOOCH<sub>3</sub>, and C<sub>2</sub>H<sub>5</sub>OH) of (<1.5 ×  $10^{-8}$ ,  $<1.8 \times 10^{-8}$ , and  $<3.7 \times 10^{-9}$ ). These upper limits indicate that, in ST11, the fractional abundance of CH<sub>3</sub>OCH<sub>3</sub> is at least an order of magnitude lower than that in Galactic hot cores, while the HCOOCH<sub>3</sub> and C<sub>2</sub>H<sub>5</sub>OH fractional abundances are comparable to the average abundances observed in the Galactic counterparts.

**4.2.** Cold Methanol: LMC N159W-South and SMC IRAS 01042-7215. *4.2.1.* N159W-South. The N159 star-forming region located south from 30 Doradus is one of the best studied areas in the LMC, hosting H II regions, young stellar clusters, *Spitzer* and *Herschel* massive YSOs, and a water maser (e.g., ref 49 and references therein; see also ref 42). As described in section 2, N159 was the target of detailed spectral line observations with single-dish telescopes. It is the brightest region in the LMC in <sup>12</sup>CO at SEST/Mopra resolution. One of the three giant molecular clouds in N159, N159W, is one of only two regions with a CH<sub>3</sub>OH detection in the pre-ALMA era.

The first high-resolution ( $\sim 1''$  or  $\sim 0.25$  pc)  $^{13}$ CO and  $^{12}$ CO (2–1) ALMA observations of N159W resolved the molecular

gas emission into filaments and detected two sources with outflows.<sup>77</sup> It was the first detection of both filamentary structure and outflows outside the Galaxy. These observations identified two main regions of high-mass star formation, which were dubbed N159W-North and N159W-South (or N159W-N and N159W-S, respectively). Both N159W-N and N159W-S are associated with *Spitzer/Herschel* YSOs.<sup>47–49,51,54</sup> Two Stage 0/I YSOs with outflows have masses >30 M<sub> $\odot$ </sub> and are associated with 1.3 mm continuum peaks, one in each N159W-N (YSO-N or *Spitzer* 053937.56-694525.4) and N159W-S (YSO-S or *Spitzer* 053941.89-694612.0; e.g., ref 49). Based on the kinematics of the molecular gas and the location of YSO-S at the intersection of two <sup>13</sup>CO filaments, it was proposed that star formation in N159W-S was triggered by the collision of two filaments ~10<sup>5</sup> years ago.<sup>77</sup>

This model was revised in ref 76, based on the 4 times higher resolution observations of CO isotopes ( $\sim$ 0."25 or 0.06 pc), which resolved the filaments in N159W-S into a complex, hub–filament structure. Multiple protostellar sources with outflows separated by 0.2–2 pc were detected along the main massive filament. They correspond to the three major 1.3 mm continuum peaks dubbed MMS-1, MMS-2, and MMS-3 (see Figure 5). The observations in ref 76 are consistent with a scenario in which a large-scale (>100 pc), rather than local ( $\sim$ 10 pc; see ref 77), collision triggered the formation of both filaments and massive protostars in N159W-S.

MMS-1 and MMS-2 continuum sources are associated with two near-infrared sources, N159 A7 "121" and "123", respectively, detected as reported in ref 78 using high-resolution (~0."2) VLT/NACO observations. The position of the Spitzer YSO (YSO-S in ref 77; see Figure 3) is offset to the west, hinting at the possibility that a cluster is being formed. No infrared source is detected toward MMS-3, indicating that it is the youngest of the three protostars. Recent VLT/KMOS observations (a pixel scale 0."2, a full width at half-maximum seeing ~0."4; PI Jacob Ward, see section A.2 for technical details) targeting YSO-S (see Figure 3) detected the K-band continuum, the Brackett-gamma emission line of hydrogen (Br $\gamma$ ), and the H<sub>2</sub> emission line toward N159 A7 121 (MMS-1) and 123 (MMS-2). As the H<sub>2</sub> and Br $\gamma$  lines trace shocks and

Figure 3. Same as Figure 2, but for N159W-S: the source with a cold methanol detection (PI Peter Schilke, see sections 4.2.1 and A.1). The ALMA 1.3 mm continuum contours are overlaid on the image in the left panel; the contour levels are (0.1, 0.3, 0.5, 0.7) mJy beam<sup>-1</sup>, the image rms noise level is 0.027 mJy beam<sup>-1</sup>.<sup>76</sup> The ALMA beam size is 0.726 × 0.723.

![](_page_6_Figure_4.jpeg)

**Figure 4.** *Left*: Three-color mosaic combining the *VLT*/KMOS *K*-band (red), ALMA CH<sub>3</sub>OH (green), and ALMA 1.3 mm (blue) images of N159W-S. The contours correspond to the 1.3 mm continuum emission with contour levels the same as in Figure 3. The yellow circle shows the catalog position of the *Spitzer* YSO.<sup>48</sup> *Right*: Three-color mosaic combining KMOS images: *K*-band (red), H<sub>2</sub> (green), and Bry (blue). The 1.3 continuum contours (the same as in the left panel) are overlaid for reference.

accretion, respectively, they can shed light on the nature of the sources and thus possible formation scenarios of COMs (e.g., non-thermal origin in shocks traced by  $H_2$ ). The right panel in Figure 4 shows a combination of the three KMOS images with the ALMA continuum contours overlaid for reference. The extended  $H_2$  emission is associated with outflows from N159 A7 121 (MMS-1) and 123 (MMS-2) detected with ALMA.<sup>76</sup> The Br $\gamma$  emission is only detected toward N159 A7 123 (MMS-2).

The most recent ALMA observations of N159W-S detected multiple CH<sub>3</sub>OH peaks throughout the region (see Figure 5; PI Peter Schilke), with the brightest emission associated with the continuum source MMS-3. The left panel in Figure 4 shows a three-color mosaic combining the KMOS *K*-band, ALMA CH<sub>3</sub>OH, and 1.3 mm continuum emission. No CH<sub>3</sub>OH emission is detected toward MMS-1 and MMS-2 that have infrared counterparts. Although these observations were designed to detect multiple COMs (e.g., CH<sub>3</sub>OH, CH<sub>3</sub>CN (methyl cyanide), HCOOCH<sub>3</sub>, CH<sub>3</sub>OCH<sub>3</sub>), only CH<sub>3</sub>OH was found. The detection of multiple peaks hints at the possibility

that there is an underlying, more extended distribution of  $CH_3OH$  that is resolved out.

Preliminary local thermodynamic equilibrium (LTE) fitting using multiple CH<sub>3</sub>OH lines (~241.7–241.9 GHz; see Table 5 below) detected toward the two brightest peaks indicate that the gas is cold ( $\sim$ 14 K). Methanol forms on grain surfaces and has to be released to the gas phase by energetic events to be detectable. The desorption mechanisms include sublimation by infrared heating by a forming star, photodesorption by UV photons, sputtering by shocks, and chemical desorption (see a discussion in section 5). None of these mechanisms is directly supported by the observations of N159W-S: the gas is cold (desorption by the infrared and UV heating is less likely) and the line widths are narrow (broad lines are expected in the shock sputtering scenario). Moreover, the average cosmic ray flux in the LMC is low, making the cosmic-ray-induced UV radiation less effective than in the Galaxy. Since the analysis of the ALMA CH<sub>3</sub>OH data is preliminary, we do not provide physical parameters for N159W-S in Table 2.

![](_page_7_Figure_1.jpeg)

**Figure 5.** Integrated intensity image of CH<sub>3</sub>OH for N159W-S, with the 1.3 mm continuum contours and the positions of the continuum peaks (MMS-1, MMS-2, and MMS-3)<sup>76</sup> overlaid. The position of the *Spitzer* YSO is indicated with the red filled circle (e.g., ref 49). The 1.3 mm continuum contour levels and the ALMA beam size are the same as in Figure 3. The ALMA synthesized beam size of the CH<sub>3</sub>OH observations (shown in the lower left corner) is 0."  $3 \times 0$ ." 3.

4.2.2. IRAS 01042-7215. IRAS 01042-7215 is a high-mass YSO (~2 × 10<sup>4</sup> L<sub> $\odot$ </sub>; e.g., refs 11 and 79; *Spitzer* YSO SSTISAGEMA J010549.30-715948.5, ref 52) located in the northeast region of the SMC bar at the outskirts of the N78 starforming region (see Figures 1 and 6). The source is well studied through near-infrared and mid-infrared spectroscopy; absorption bands due to H<sub>2</sub>O ice, CO<sub>2</sub> ice, and silicate dust are detected, while prominent PAH bands and ionized metal lines are not detected.<sup>10,11,59,79</sup> No CH<sub>3</sub>OH ice has been detected toward IRAS 01042-7215.

Recent VLT/SINFONI K-band observations (a pixel scale of 0."1, a full width at half-maximum seeing ~0."6)<sup>80</sup> detected the Br $\gamma$  and H<sub>2</sub> emission lines toward IRAS 01042-7215.<sup>80</sup> Figure 7 shows a three-color mosaic combining the SINFONI K-band continuum, H<sub>2</sub>, and Br $\gamma$  images. The SINFONI image reveals a single compact embedded source ( $A_v = 16 \pm 8 \text{ mag}$ ) with little or no extended line emission. The measured H<sub>2</sub> emission line ratios are consistent with expectations for shocked emission.<sup>81</sup>

The high-resolution ( $\sim$ 0."22–0."37 or  $\sim$ 0.07–0.11 pc at the distance of the SMC) 1.2 mm ALMA observations detected two continuum peaks, P1 and P2/P3, toward IRAS 01042-7215. P2/P3 is further resolved into two sources (P2 and P3) corresponding to the CH<sub>3</sub>OH emission peaks where multiple CH<sub>3</sub>OH transitions are detected (Figure 8; see also ref 19).

The 1.2 mm continuum source P1 is associated with the highmass YSO corresponding to the IRAS source, while no infrared sources are detected at the positions of P2 and P3 (see Figure 7 and ref 19). P2 and P3 correspond to the two CH<sub>3</sub>OH emission peaks in the region; no CH<sub>3</sub>OH is detected toward P1 (Figure 8 and see also ref 19). Besides CH<sub>3</sub>OH, CS, C<sup>33</sup>S, SO, SO<sub>2</sub>, H<sup>13</sup>CO<sup>+</sup>, H<sup>13</sup>CN, SiO are detected toward P2/P3, but no COMs larger than CH<sub>3</sub>OH.

The rotation diagram analysis of the CH<sub>3</sub>OH lines for IRAS 01042-7215 P2 and P3 suggests that the temperature of the CH<sub>3</sub>OH gas is low (~20 K), well below the sublimation temperature of the CH<sub>3</sub>OH ice (~80 K).<sup>82</sup> This is another example of a source in the Magellanic Clouds with the detection of "cold methanol". The CH<sub>3</sub>OH abundances relative to H<sub>2</sub> for P2 and P3 are an order of magnitude lower than those for hot cores A1 and B3 in N113 (see Table 2 and section 4.3). The origin of CH<sub>3</sub>OH gas in P2/P3 is still under debate. The authors of ref 19 suggest that a possible origin could be sputtering of the

The continuum contour levels are (3, 6, 10, 20)  $\times$  21 mJy beam<sup>-1</sup>, the 1.2 mm image rms noise level. The ALMA synthesized beam size is 0."35  $\times$  0."22.

![](_page_8_Figure_4.jpeg)

**Figure 7.** Three-color mosaic of the IRAS 01042-7215 field combining the *VLT/SINFONI K*-band (red),  $H_2$  (green), and Br $\gamma$  (blue) images.<sup>80</sup> Red contours correspond to the ALMA 1.2 mm continuum emission with contour levels the same as in Figure 6.

ice mantles by shocks triggered by the outflow from nearby YSOs, or chemical desorption of  $CH_3OH$  from dust surfaces. The presence of shocked but cold  $CH_3OH$  gas has been suggested in Galactic infrared dark clouds, indicating that  $CH_3OH$  may be tracing relatively old shocks (e.g., ref 83).

4.3. Hot Cores with COMs More Complex than Methanol: LMC N113 A1 and B3. To date, COMs with more than six atoms have only been reliably detected in the Magellanic Clouds toward two sources, both in the LMC N113 star-forming region. The physical and chemical characteristics of N113 make it one of the most interesting star-forming regions in the LMC. Like N159, it was the target of detailed spectral line studies with single-dish telescopes (see section 2) that resulted in the detection of  $CH_3OH$ .<sup>17</sup>

N113 contains: (1) one of the most massive ( $\sim 10^5 M_{\odot}$ ) and richest GMCs in the LMC;<sup>27</sup> (2) signatures of both recent (H $\alpha$  emission) and ongoing (e.g., maser and bright infrared emission) star formation;<sup>34,84</sup> (3) signatures of star formation triggered by winds from massive stars; (4) the largest number of

![](_page_8_Figure_9.jpeg)

**Figure 8.** CH<sub>3</sub>OH integrated intensity image (the average of the CH<sub>3</sub>OH  $5_{-1,5}$ - $4_{-1,4}$  E and  $5_{0,5}$ - $4_{0,4}$  A<sup>+</sup> lines) of IRAS 01042-7215 in the SMC. The 1.2 mm continuum contours are overlaid; the contour levels and the size of the ALMA synthesized beam shown in the lower left corner are the same as in Figure 6.

 $\rm H_2O$  and OH masers and the brightest  $\rm H_2O$  maser in the entire LMC;  $^{38,42,84-86}$  and (5) it has among the highest concentrations of *Spitzer/Herschel* Stage 0-II YSO candidates in the LMC.  $^{47,48,51,53,54}$ 

Mid-infrared sources, maser emission, and compact H II regions in the central part of the GMC associated with the extended gas and dust emission, reveal sites of the current star formation in N113 (see Figure 9). The *Spitzer*  $(3.6-160 \ \mu m)$  and *Herschel*  $(160-500 \ \mu m)$  images with resolutions ranging from ~2" to 38" show that this region is dominated by three bright sources, which were identified as  $30-40 \ M_{\odot}$  Stage I YSOs (YSO-1, YSO-3, and YSO-4 in Figure 9: *Spitzer* sources 051317.69-692225.0, 051325.09-692245.1, and 051321.43-692241.5, respectively)<sup>48</sup> and are characterized by distinct physical conditions (see refs 48 and 87, as well as Oliveira et al., manuscript submitted to Monthly Notices of the Royal Astronomical Society).

Detailed *Spitzer* and *Herschel* studies on the YSO population in N113 were followed by ALMA Band 6 (~1.3 mm) observations at 0.18 pc (or ~0."8) resolution in the molecular transitions that probe a wide density range  $(10^2-10^7 \text{ cm}^{-3})$  to

![](_page_9_Figure_2.jpeg)

Figure 9. Left: Same as in Figure 2, but for N113 A1 (top) and B3 (bottom) hot cores. The contours in the left panel correspond to the 1.3 mm continuum emission.<sup>18</sup> The contour levels are  $(5, 10, 20, 50) \times$  the image rms noise level of 0.1 mJy beam<sup>-1</sup>.

study both the dense clumps/cores and the lower density gas in the inter-clump regions. The ionized gas and outflow tracers were also included in the program. These observations resulted in a serendipitous discovery of COMs CH<sub>3</sub>OH, HCOOCH<sub>3</sub>, and CH<sub>3</sub>OCH<sub>3</sub> toward two locations in the region<sup>18</sup> (see Figures 9 and 10). The detected transitions are listed in Table 5 below. This was the first conclusive detection of COMs more complex than methanol outside the Galaxy and in a lowmetallicity environment. COMs were detected toward two 1.3 mm continuum sources, A1 and B3, in the field around Spitzer YSO-3 ("Region A" in ref 18) and YSO-1 ("Region B"). Figure 9 shows three-color mosaics covering A1 and B3 combining nearinfrared bands with 1.3 mm contours overlaid, as well as a larger scale environment in N113 traced by the *Spitzer* 4.5 and 8.0  $\mu$ m, and H $\alpha$  emission. Figure 10 shows the integrated intensity CH<sub>3</sub>OH, CH<sub>3</sub>OCH<sub>3</sub>, and HCOOCH<sub>3</sub> images of Regions A and B.

A1 and B3 are compact (diameter  $D \approx 0.17$  pc) and are associated with H<sub>2</sub>O (A1 and B3) and OH (A1) masers. H<sub>2</sub> column densities of  $(8.0 \pm 1.2) \times 10^{23}$  and  $(7.0 \pm 0.9) \times 10^{23}$ cm<sup>-2</sup> and number densities of  $\sim 1.6 \times 10^6$  and  $\sim 1.4 \times 10^6$  cm<sup>-3</sup> for A1 and B3, respectively, were estimated using the 1.3 mm continuum data. The LTE analysis of six CH<sub>3</sub>OH transitions resulted in rotational temperatures and total column densities  $(T_{rott} N_{rot})$  of  $(134 \pm 6 \text{ K}, 1.6 \pm 0.1 \times 10^{16} \text{ cm}^{-2})$  and  $(131 \pm 15 \text{ K}, 6.4 \pm 0.8 \times 10^{15} \text{ cm}^{-2})$  for A1 and B3, respectively.<sup>18</sup> These sizes, number and column densities, and temperatures of A1 and B3 are consistent with classic hot cores observed in the Galaxy. COMs emission and association with masers are also among the main characteristics of hot cores. These are the first bona fide detections of complex hot-core chemistry outside the Galaxy.

The (CH<sub>3</sub>OH, CH<sub>3</sub>OCH<sub>3</sub>, HCOOCH<sub>3</sub>) column densities are  $(16 \pm 1, 1.8 \pm 0.5, 1.1 \pm 0.2) \times 10^{15}$  cm<sup>-2</sup> for A1 and  $(6.4 \pm 0.8, 1.2 \pm 0.4, <0.34) \times 10^{15}$  cm<sup>-2</sup> for B3. Column densities for HCOOCH<sub>3</sub> and CH<sub>3</sub>OCH<sub>3</sub> were estimated using the same  $T_{\rm rot}$ as for CH<sub>3</sub>OH, assuming that these molecular species are located in the same region as CH<sub>3</sub>OH in A1 and B3.

The (CH<sub>3</sub>OH, CH<sub>3</sub>OCH<sub>3</sub>, HCOOCH<sub>3</sub>) fractional abundances with respect to H<sub>2</sub> are (20 ± 3, 2.2 ± 0.7, 1.4 ± 0.4) × 10<sup>-9</sup> for A1 and (9.1 ± 1.7, 1.7 ± 0.7, <0.5) × 10<sup>-9</sup> for B3 (see Table 2). The CH<sub>3</sub>OH fractional abundances in A1 and B3 are over an order of magnitude larger than an upper limit estimated for ST11 in ref 73 (see section 4.1). Table 3 lists CH<sub>3</sub>OH, CH<sub>3</sub>OCH<sub>3</sub>, and HCOOCH<sub>3</sub> fractional abundances for a set of Galactic hot cores. When scaled by a factor of 2.5 to account for the lower metallicity in the LMC (the ratio between the solar metallicity and the metallicity of the LMC, assuming  $Z_{LMC} = 0.4 Z_{\odot}$ ), the abundances of COMs detected in N113 are comparable to those found at the lower end of the range in Galactic hot cores. This was a surprising result because previous observational and theoretical studies indicated that the abundance of CH<sub>3</sub>OH in the LMC is very low. The authors of ref 18

![](_page_10_Figure_2.jpeg)

**Figure 10.** Integrated intensity images for CH<sub>3</sub>OH (*top panel*; made using the channels corresponding to all CH<sub>3</sub>OH transitions in the 216.9 GHz spectral window; see Table 5), CH<sub>3</sub>OCH<sub>3</sub> (*middle panel*; the  $13_{0,13}$ – $12_{1,12}$  transition); and HCOOCH<sub>3</sub> (*bottom panel*; integrated over all detected transitions) for the A1 (*left column*) and B3 (*right column*) hot cores in the N113 star-forming region. The H<sub>2</sub>O and OH masers are indicated. The white contours correspond to the 1.3 mm continuum emission; the contour levels are the same as in Figure 9. The red contours in the top right panel correspond to the CH<sub>3</sub>OH emission with contour levels of (3, 5, 7) × 21 mJy beam<sup>-1</sup>, the rms noise level of the CH<sub>3</sub>OH integrated intensity image. The image shows the CH<sub>3</sub>OH detection in other spots in the region ("Region B" in ref 18) where no other COMs are detected. The results presented in this figure were reported in ref 18. The ALMA beam size is shown in the lower left corner in each image.

concluded that COMs observed in the N113 hot cores could originate either from grain surface chemistry or in postdesorption gas chemistry.

The quartet  $J = 2_K - 1_K$  of CH<sub>3</sub>OH at ~96.7 GHz was later detected serendipitously toward N113 with ALMA in the project targeting two transitions (1–0 and 2–1) of three CO isotopes (<sup>12</sup>CO, <sup>13</sup>CO, and C<sup>18</sup>O) toward three LMC and three SMC star-forming regions with a resolution of ~2″ (or ~0.48 pc). N113 is the only region in this sample with CH<sub>3</sub>OH detection. The spectral window with the CH<sub>3</sub>OH line was dedicated to the continuum observations and has a spectral resolution of ~50 km s<sup>-1</sup>. Such low spectral resolution does not allow for any quantitative analysis, but surprisingly the data revealed several additional well-defined CH<sub>3</sub>OH peaks and extended emission in Region B (see Figure 11). The CH<sub>3</sub>OH emission reported in ref 18 was limited to two compact sources (hot cores A1 and B3), with some fainter emission detected in other locations in Region B (see Figure 10); however, it was unclear whether the latter traces physically distinct sources or shocked lobes of the outflows.

In addition to hot cores, the ~96.7 GHz CH<sub>3</sub>OH emission is detected toward continuum sources B4, B7, and B6 in Region B and D1–D4 located toward the south (Figure 11; Sewiło et al., manuscript in preparation). In Region A, the ~96.7 GHz CH<sub>3</sub>OH emission peak coincides with hot core A1; however, the emission extends toward the south.

The ~96.7 GHz CH<sub>3</sub>OH emission peaks in Regions A and B overlap with the SiO (5-4) peaks (with some faint extended emission visible throughout Region B, see Figure 12; ref 18 and Sewiło et al., manuscript in preparation), tracing shocks. The

same regions are associated with the DCN (3-2) emission, indicating their youth, and are distributed along the dense gas filament. The observational and theoretical studies indicate that the abundance of all deuterated species strongly depends on temperature: it drops rapidly with increasing gas temperature as an object evolves (see, e.g., refs 88-91).

#### 5. THEORY

We can gain some insight as to the origin of the COMs detected in the Magellanic Clouds by comparing observations with current astrochemical theories of Galactic COM production in star-forming regions. Here we briefly review COM formation mechanisms and how they have been applied to low-metallicity environments.

5.1. Complex Molecule Formation in Star-forming **Regions of the Milky Way.** In the Galaxy, the largest COMs have until now been found primarily in the hot molecular cores associated with massive protostars, as well as with the so-called hot corinos found in regions of low-mass star formation (e.g., ref 95). In cold, dense molecular clouds, some of these organics have been known to be present for quite some time: HNCO, HCOOH, CH<sub>2</sub>CO, CH<sub>3</sub>CHO, CH<sub>3</sub>OH.<sup>96</sup> More recently, the larger "hot-core" COMs, including CH<sub>3</sub>OCH<sub>3</sub> and HCOOCH<sub>3</sub>, have also been detected in several cold clouds.98-102 These detections have raised several challenges for existing theories of COM formation. These include the long-standing problem of identifying the mechanism responsible for returning ice-mantle molecules to the gas in cold clouds, and the fact that radical reactions on 10 K grains will not occur. In the case of the cold methanol detected in the LMC, it would appear that reactive desorption (i.e., using part of the energy released upon formation) is a plausible explanation.<sup>103,104</sup>

Hot cores are regions of high gas density and extinction where elevated dust temperatures have led to the sublimation of molecular ice mantles that have previously grown on cold dust grains. The first model of hot-core chemical evolution was

![](_page_11_Figure_10.jpeg)

**Figure 11.** Single-channel maps corresponding to the peak of the unresolved rotational transition quartet  $J = 2_K - 1_K$  of CH<sub>3</sub>OH at 96.7 GHz for regions in N113 around and south of B3 (*top*) and toward A1 (*bottom*) hot cores (Sewiło et al., manuscript in preparation; ALMA 12-m Array data). The white 1.3 mm continuum contours in the left panel are the same as in Figure 9. The white CH<sub>3</sub>OH contours in the right panel correspond to (3, 5, 7)× rms noise level of the CH<sub>3</sub>OH single-channel map of 0.32 mJy beam<sup>-1</sup>. The ALMA beam size (2."15 × 1."66) for the CH<sub>3</sub>OH observations is shown in the lower left corner in all images.

![](_page_12_Figure_2.jpeg)

**Figure 12.** SiO (5–4) integrated intensity images of N113 A1 (*left*) and B3 (*right*) hot cores (Sewiło et al., manuscript in preparation). The contours are the same as in Figure 9 (1.3 mm; *white*) and Figure 10 (CH<sub>3</sub>OH; *red*). The positions of H<sub>2</sub>O and OH masers, and 1.3 mm continuum sources associated with the CH<sub>3</sub>OH emission are indicated. The ALMA beam size ( $0.^{"}98 \times 0.^{"}61$ ) is shown in the lower left corner in both images.

presented in ref 105. This involves a long period of cold (~10 K) chemistry during which molecules form by gas-phase reactions and on dust grains, as the gas freezes out; this chemistry is similar to that found in cold dark clouds (e.g., ref 106). At some point gravitational collapse ensues, a protostar is formed, and the resulting large increase in luminosity heats the surrounding envelope of gas and dust to temperatures above about 100 K, leading to the sublimation of ice mantles and the formation of the hot core/corino. Further refinements to this picture have been (a) the addition of a slow "warm-up" phase that can allow UV photolysis and radical-radical reactions to occur in the ice mantles, prior to formation of the hot core proper,<sup>107</sup> and (b) gas-phase synthesis in the hot core, driven by the sublimated molecules.<sup>108</sup> Further refinements have included the spatiotemporal evolution of the gas-grain chemistry.<sup>109,110</sup>

Thus, within this simple picture, the complex molecules observed in hot cores can have four chemical origins: (1) formation in cold gas followed by freeze-out on dust; (2) formation on the surfaces of cold (10 K) dust grains; (3) formation in UV-photolyzed ice mantles at  $\sim$ 30 K; or (4) *in situ* formation in hot-core gas following ice sublimation.

5.1.1. Cold Gas-Phase Reactions in Dark Clouds. Cosmicray ionization of molecular hydrogen drives dense cloud chemistry by initiating sequences of ion-neutral and neutralneutral reactions. This chemistry leads to the production of CO and many of the simple molecules detected in dark interstellar clouds. The complex molecules produced tend to be long hydrocarbon chains and associated radicals, such as the cyanopolyynes and various carbenes. The dark cloud TMC-1 in Taurus is recognized as the best example of this chemistry (e.g., ref 111), and chemical modeling demonstrates that gasphase chemistry can account quite well for its composition (e.g., ref 112). It is now appreciated that methanol is formed entirely on dust grains (see section 5.1.2), and so some (non-thermal) desorption mechanism is required to explain its presence in dark clouds like TMC-1, since dust temperatures are never sufficiently high for methanol and water to desorb. However, in dense cores where low-mass protostars are forming, it appears that some dust heating (to  $\sim 30-35$  K) has occurred, and this can lead to the sublimation of more-volatile molecules. In this Warm Carbon Chain Chemistry (WCCC), sublimation of large abundances of methane from the ice mantles greatly increases the efficiency of carbon-chain growth.<sup>113</sup> Although we do not discuss CH<sub>4</sub> injection further, the similarly warm dust

temperatures found in the Magellanic Clouds may make this a viable route to widespread carbon chain formation there.

5.1.2. Cold Grain-Surface Reactions. Ice mantles grow on cold dust grains through the sticking of atoms of O, C, and N followed by reactions with H atoms to form H<sub>2</sub>O, CH<sub>4</sub>, and NH<sub>3</sub>. Molecules formed in the gas, such as CO and N<sub>2</sub>, can also accrete and become incorporated in the mantle. Unsaturated molecules can undergo (tunneling) addition reactions with hydrogen atoms to produce molecular radicals that can further react and form new molecules (e.g., ref 114). Figure 13 shows that, in the case of CO, these processes can lead to a rich organic chemistry (e.g., ref 115) through the growth of linear chains by single atom additions and their subsequent saturation. This surface scheme can explain the presence of CH<sub>3</sub>OH and many of the COMs known in hot cores and originally made predictions<sup>116</sup> for new surface molecules (not shown) that were subsequently detected: glycolaldehyde, 117,118 ethylene glycol,<sup>119</sup> acrolein, and propionaldehyde.<sup>120</sup> Numerous surface chemistry experiments have validated many of these addition processes.<sup>121-123</sup>

5.1.3. COM Chemistry Driven by Sublimated Ice Mantles. The authors of ref 108 demonstrated that differences in mantle composition could, following sublimation, account for the chemical differentiation seen in the Orion-KL star-forming region. Rather than calculate the mantle composition *ab initio*, they assumed a composition based on observations and showed that the relative presence, or not, of methanol and ammonia could drive different chemistries in the hot gas (see also refs 124 and 125). In ref 126, it was first suggested that self-methylation of methanol could be the source of dimethyl ether in hot cores, although the authors attributed its origin to be protostellar outflows rather than grain–surface chemistry. The self-methylation reaction is

$$CH_3OH_2^+ + CH_3OH \rightarrow CH_3OCH_4^+ + H_2O$$
(1)

where the neutral  $CH_3OCH_3$  molecule is produced in reactions with either an electron or a base, such as ammonia. The authors of ref 127 showed, based on laboratory experiments, that apart from  $CH_3OCH_3$ , many more large ethers and esters could be formed in this manner, in reactions involving ethanol, propanol, and butanol.<sup>128</sup> Figure 13 includes alkylation reactions between protonated methanol and ethanol, the neutral alcohols, and formic acid. Methyl formate formation by methylation of HCOOH has also been studied in the laboratory<sup>129</sup> and shown to be a viable mechanism. In these experiments, the *trans*-

![](_page_13_Figure_1.jpeg)

**Figure 13.** Interstellar gas–grain surface chemistry. Molecules involved in surface reactions are in black. Hydrogen atom addition to unsaturated molecules creates reactive radicals and additions of C, O and N atoms, allows a rich organic chemistry seeded by carbon monoxide to develop. Broken arrows indicate reactions with activation energy barriers; where 2H is shown, a barrier penetration reaction followed by an exothermic addition is implicitly indicated. Once these ice mantles have been sublimated into the hot-core gas, methanol and ethanol can become protonated and take part in ion–molecule alkyl cation transfer reactions with themselves and with other molecules that were formed in the ices. These processes are denoted in blue, and each arrow indicates the initial ion–molecule reaction and the production of the neutral COM, through either electron dissociative recombination or proton transfer to ammonia (adapted from ref 115 and references therein).

HCOOH conformer of formic acid produced the protonated form of *trans*-HCOOCH<sub>3</sub>; electron dissociative recombination, or proton transfer (see below), would then lead to the neutral ester. However, apart from one detection of *trans*-HCOOCH<sub>3</sub>,<sup>130</sup> it is the more stable *cis*-HCOOCH<sub>3</sub> conformer that is found in hot cores. It has therefore been suggested that interconversion between *trans*-HCOOCH<sub>3</sub> and *cis*-HCOOCH<sub>3</sub> structures could occur in the proton loss process.<sup>131</sup> Chemical models have demonstrated that this is a very competitive pathway to HCOOCH<sub>3</sub> around protostars,<sup>132</sup> assuming that interconversion proceeds with high efficiency.<sup>133</sup> Of the COM products shown in Figure 13, apart from dimethyl ether and methyl formate, both ethyl formate and ethyl methyl ether have now been detected.<sup>134,135</sup>

A problem with this scenario has been that experiments on electron dissociative recombination of protonated COMs show that recovery of the neutral molecule occurs with a probability much lower than previously assumed, typically <5% as compared to 100% (e.g., ref 136), and subsequently to COM abundances much lower than observed. However, if NH<sub>3</sub> is injected from grain mantles at moderate abundances, com-

parable with those measured in Galactic ices,<sup>137</sup> then proton transfer, e.g.,

$$CH_3OH_2^+ + NH_3 \rightarrow CH_3OCH_3 + NH_4^+$$
(2)

can dominate COM formation and mitigate against the destructive effects of electron recombinations.<sup>132,138</sup>

As also shown in Figure 13, gas phase COM formation driven by alkyl cation transfer reactions involving surface-formed HNCO and NH<sub>2</sub>CHO could plausibly be a source of new molecules, perhaps explaining the hot-core detections of methyl isocyanide (CH<sub>3</sub>NCO) and acetamide (NH<sub>2</sub>COCH<sub>3</sub>).<sup>139,140</sup> However, the associated gas phase reactions have not yet been studied experimentally or theoretically and so should be regarded as speculative.

5.1.4. Radical Reactions in Icy Grain Mantles. As well as chemical reactions on grain surfaces driven by accretion of reactive species, it is also known that the ices can undergo bulk processing due to radiation damage caused by photons and energetic particles. Cosmic rays interact directly with icy mantles and recently chemical models have been developed to explore their effects on COM formation (see ref 141 and references therein). The environment of young protostars receives large doses of UV and EUV radiation.<sup>142</sup> Even in dark clouds, a weak ambient flux of internal UV photons will exist<sup>143</sup> as energetic electrons produced by cosmic-ray ionization of molecular hydrogen can subsequently collide with, and excite, other H<sub>2</sub> molecules which undergo de-excitation by emission of Lyman and Werner band photons. The resulting UV flux is  $\sim 10^3$ photons  $s^{-1}$  cm<sup>-2</sup>, which can be significant for chemistry in dense clouds. Laboratory experiments on UV photolysis of interstellar ice analogs show that an extensive organic chemistry can occur, primarily through reactions involving various radials produced from the major (parent) ice species (e.g., ref 144). Cold H additions to CO (see section 5.1.2) have also to be considered since interstellar organic synthesis by photolysis requires that the methanol be present ab initio.144,14

Early theoretical models for organic synthesis from the recombination of radicals on cold grains appealed to physically unrealistic processes to attain the high mobilities needed for heavy particle migration and reaction.  $^{146-150}$  Detailed modeling has shown that sustained UV photolysis and warming during the early stages of hot-core evolution can produce many new organics.<sup>107</sup> In this picture, the ices are subjected to the Prasad-Tarafdar UV photons during the initial cold phase of core formation, producing a population of radicals. This irradiation can continue as the core is being gradually (as opposed to instantaneously) heated-the so-called "warm-up" phase.<sup>107,151</sup> When the dust grain temperature reaches, and can be maintained close to, about 30 K, the associated increase in radical mobility allows them to migrate and react. Radicalradical recombinations between HCO, CH<sub>3</sub>O, CH<sub>2</sub>OH, COOH, and other simple radicals (e.g., CH<sub>3</sub>, CH<sub>2</sub>, NH<sub>2</sub>, CN, OH) then produce many of the COMs observed in hot cores.<sup>134,152,153</sup>

**5.2. Models of COM Formation in the Magellanic Clouds.** Here we summarize and discuss theoretical models of COM formation at reduced metallicity in the light of recent observations.

5.2.1. Chemical Models of the LMC and SMC. The authors of ref 154 considered the chemical evolution of putative dark clouds in the LMC and SMC at the appropriate elemental depletions. They considered the purely gas-phase chemistry of fairly simple molecules, with only CH<sub>3</sub>OH and CH<sub>2</sub>CO being

the only COMs. These models could produce  $CH_3OH$  abundances of  $\sim 10^{-8}$ ; however, the main formation mechanism was through a radiative association process that is no longer considered viable.

More recently, gas-grain models of the LMC and SMC were developed.<sup>155,156</sup> Again, cold dark clouds were modeled for a wider range of physical parameters, including appropriately warmer gas and dust temperatures. In these models CH<sub>3</sub>OH was formed by CO hydrogenation on dust grains. For the LMC, they found that molecular abundances similar to Milky Way dark clouds could be obtained, whereas for the SMC the abundances were lower for most molecules. The model predictions were compared to several star-forming regions in the LMC (as no data on Magellanic dark clouds then existed): N159W, N159S, N160, and 30 Dor-10. When compared to the Magellanic source N159W with a thermal methanol detection, the calculated abundances were found to be  $\sim 10-10^3$  times lower than determined in ref 16. The reason for this discrepancy was explained as being due to the warm dust temperatures, appropriate for Magellanic dark clouds, that were considered in the models. Dust temperature affects grain-surface chemistry and can inhibit methanol formation since, for temperatures above about 15 K, hydrogen atoms will desorb before they can react with CO. Above about 25 K, CO molecules residing in CO-rich outer layers of the ice mantle will also sublimate, whereas those trapped in the H<sub>2</sub>O ice matrix require higher dust temperatures.<sup>157</sup> In both the LMC and SMC models, gaseous  $NH_3$  abundances of ~10<sup>-8</sup> were found. For models with dust temperatures more similar to the Milky Way ( $\sim 10-15$  K), the dust ice mantles are predicted to contain large fractions of CH<sub>3</sub>OH ( $\sim$ 10–40%) and NH<sub>3</sub> ( $\sim$ 1–7%). Hence, the presence of CH<sub>3</sub>OH in the Magellanic Clouds points to formation in a cold pre-hot-core phase.

The authors of ref 158 studied the formation of ice mantles in the Magellanic Clouds but instead employed a correct stochastic calculation of the grain chemistry. The relative composition of ices comprising of H<sub>2</sub>O, CO, CO<sub>2</sub>, CH<sub>3</sub>OH, NH<sub>3</sub> and CH<sub>4</sub> were calculated as a function of the interstellar UV radiation field. The CH<sub>3</sub>OH and NH<sub>3</sub> ice fractions were found to be lower (~few %) than those reported in refs 155 and 156, and more compatible with those of Galactic ices (ref 137).

The authors of ref 159 reported the first bona fide hot-core models of the Magellanic Clouds. Their model was a standard three-phase model (cold quasi-static phase, collapse phase with or without "warm-up", and hot-core phase; see section 5.1) and included the radical chemistry induced during the "warm-up" phase as well as many of the COMs known in Galactic hot cores (refs 107 and 152; see section 5.1.4). When compared to the N113 observations, only one of the models (a 100 K core in which the initial phase of core formation proceeded at 10 K, Model 1) reproduced the observed CH<sub>3</sub>OH abundances in both A1 and B3 at times (post-sublimation) when CH<sub>3</sub>OCH<sub>3</sub> and HCOOCH<sub>3</sub> had non-trivial abundances. As CH<sub>3</sub>OH is the proposed parent of CH<sub>3</sub>OCH<sub>3</sub> and HCOOCH<sub>3</sub> both in grainsurface reactions (see section 5.1.4) and in ion-molecule reactions (see Figure 13), the comparison of predicted CH<sub>3</sub>OCH<sub>3</sub>/CH<sub>3</sub>OH and HCOOCH<sub>3</sub>/CH<sub>3</sub>OH ratios with observations provides the most stringent tests of their origin (see section 5.2.2).

Overall, these models indicate that the hot cores in the Magellanic Clouds must have undergone a period of chemical evolution when the dust was cold, as in theories of Galactic hotcore formation. 5.2.2. Models for COM *lce–Gas Synthesis*. Given the importance of  $NH_3$  for gaseous COM formation, the Magellanic Clouds offer a potential opportunity to test this scenario in a low-metallicity environment. In ref 159, it was emphasized that the sublimation of COM-containing ice mantles into the hot gas, not active formation *in situ*, as the possible source of Magellanic COMs. Post-sublimation gas-phase synthesis (see section 5.1.3) has not yet been studied in the context of the Magellanic Clouds, and here we report relevant model calculations as a first approximation.

The calculations were performed with the dynamicalchemical model of ref 132, but modified according to the simplest version of these models in which the physical conditions are fixed in time and the ices are injected instantaneously into the hot gas at t = 0 (cf. ref 108), as opposed to computing the physical and chemical evolution of the core (e.g., gravitational collapse, protostellar luminosity heating, time-dependent molecule desorption). Table 4 lists the assumed ice mantle compositions. These were obtained by scaling the ice abundances from Table 1 of ref 132 to the elemental depletions observed in the SMC and LMC clouds as listed in Table 1 of refs 155  $(f_{LMC,i})$  and 156  $(f_{SMC,i})$ , respectively. The (C, O, N) scaling factors (1/f) are (0.41,0.46, 0.21) for the LMC and (0.20, 0.22, 0.064) for the SMC; for each molecule listed in Table 4, we used the averaged 1/f of its corresponding elements to determine initial ice abundances in the LMC/SMC from their Galactic values used in ref 132. Typical hot-core physical conditions were assumed:  $n_{\rm H_2} = 5 \times$  $10^7$  cm<sup>-3</sup>, *T* = 150 K, and a cosmic-ray ionization rate  $\zeta$  = 3 ×  $10^{-17}$  s<sup>-1</sup>. The chemical network is as discussed in ref 132. Figure 14 shows COM chemical evolution in hot-core models applicable to the LMC and SMC. Generally, one can notice a decrease of all gas phase abundances by a factor of a few depending on the elemental depletion of C, N, and O in the two galaxies. However, the stronger N depletion relative to C and O (by a factor of 2 and 4 for the LMC and SMC, respectively) induces a more pronounced decrease of NH3 relative to other ice species.

As reported in ref 132, a decrease of the injected ice mantle  $\rm NH_3/CH_3OH$  abundance ratio from ~1 decreases the production efficiency of COMs; for  $\rm CH_3OCH_3$  and  $\rm HCOOCH_3$  the Magellanic Cloud abundances are lower by a factor of 3 for the LMC and of 5 for the SMC. The  $\rm NH_3$  abundance is not observationally well-constrained in the LMC and SMC and is unknown in the N113 region. An ammonia abundance of ~4 ×  $10^{-10}$  was measured in N159W in the LMC,<sup>36</sup> and Figure 15 shows that systematically reducing the injected  $\rm NH_3$  abundance from ices dramatically lowers the COM abundances. However,

![](_page_15_Figure_2.jpeg)

**Figure 14.** Chemical evolution in hot-core models of the LMC (*left panel*) and SMC (*right panel*). Ice mantles with the compositions of Table 4 are instantaneously injected into the gas at t = 0.

any decline in COMs below an NH<sub>3</sub> abundance of  $\sim 10^{-8}$ , down to the level measured in ref 36, is halted as electron dissociative recombinations come to dominate the loss of molecular ions. Although models of ice formation in the Magellanic Clouds do predict NH<sub>3</sub>/H<sub>2</sub>O mantle fractions sufficiently large to allow efficient ion-molecule formation in the LMC (see section 5.2.1), NH<sub>3</sub> observations of N113 and other COM-containing regions are clearly required to validate the efficacy of this process.

The observed abundances of CH<sub>3</sub>OCH<sub>3</sub> and HCOOCH<sub>3</sub> in the A1 and B3 hot cores of N113 (see Table 3) can be reproduced in the models of Figure 14, despite the lower elemental depletions. However, as in the case of Galactic hotcore models these do not occur at a time when the CH<sub>3</sub>OCH<sub>3</sub>/ CH<sub>3</sub>OH and HCOOCH<sub>3</sub>/CH<sub>3</sub>OH abundance ratios have their observed values (Figure 16). In the LMC, when the methanol abundance is ~10<sup>-8</sup>, the observed CH<sub>3</sub>OCH<sub>3</sub>/CH<sub>3</sub>OH ratios in A1 (~0.1) and B3 (~0.2) are about an order of magnitude higher than the calculated values (~0.003) is about a factor 20 too low.

In ref 159, the authors claimed a very good agreement with the abundances of ref 18 to within a factor of 5. However, calculated abundances and the observed abundances were presented as relative to total hydrogen density and molecular hydrogen density, respectively. Correcting the abundance comparison by the factor of 2 means that for  $CH_3OCH_3$  in A1 and B3, the models overpredict the abundances by factors of 12-20; only the calculated abundances of  $CH_3OH$  and  $HCOOCH_3$  in A1 agree to within a factor of 5.

When a detailed treatment of the collapse physics is included in hot-core chemistry models, a monotonic increase in the radial gas and dust temperatures occurs as a function of the increasing (accretion) luminosity of the protostar (e.g., ref 109). In the case of Galactic hot cores/corinos, ref 132 showed that molecular *recondensation* may be just as chemically important as molecular depletion onto dust in cold cores, and sublimation from them in hot cores. This can occur if the accretion onto the protostar is not monotonic but sporadic.<sup>160</sup> Once grains have been raised to a temperature of about 120 K or more, most of the ice mantle is removed and, as they cool to 50 K or lower in about 100 years, selective recondensation can occur due to the differing binding energies for physisorption. Production of organic molecules ensues in the brief post-sublimation period, as in the standard

model, except that the products subsequently condense as ices. It was demonstrated in ref 132 that the observed large  $CH_3OCH_3/CH_3OH$  and  $HCOOCH_3/CH_3OH$  ratios could be reproduced due to the relatively higher binding energy of

![](_page_15_Figure_11.jpeg)

 $CH_3OH$ . This may be a fundamental process for the organic chemistry of material near protostars, as between sublimation–recondensation events, there can be a mantle-driven gaseous chemistry leading to the dust grains being coated with the products as they cool. This scenario remains to be evaluated in the context of Magellanic Cloud hot cores.

# 6. DISCUSSION

Although single-dish observations provided the first detections of methanol in two bright regions in the LMC (N159 and N113), it was ALMA with its unprecedented angular resolution and sensitivity that has started and continue revolutionizing the field of complex organic chemistry in low-metallicity environments. To date, the sample of sources with COMs detection is very small and diverse. Only two bona fide hot cores with COMs are known in the Magellanic Clouds, both in the N113 starforming region in the LMC (N113 A1 and B3).<sup>18</sup> Another hot core in the LMC (ST11) was reported in ref 73, but no methanol or other COMs were detected. The detection of methanol was reported for two other sources, one in the LMC (N159W-S, section A.1) and one in the SMC (IRAS 01042-7215),<sup>19</sup> but not in hot cores ("cold methanol"). Several sources in N113 (in addition to two hot cores) are associated with methanol, but due to a very low spectral resolution of the observations, a determination of their physical parameters based on the existing data is currently impossible. Table 5 summarizes the COM transitions detected in the Magellanic Clouds with ALMA.

No firm conclusions about complex organic chemistry under reduced metallicity conditions can be drawn based on the current sample of sources with the detection of COMs. However, some general trends are noticeable.

None of the sources with a COMs detection is associated with an infrared source: COMs are detected toward mm continuum sources in the vicinity of bright Spitzer YSOs. ST11 with no COMs detection but with evidence for hot-core chemistry is the only source associated with the infrared source. In fact, this is the brightest Spitzer YSO in the entire N144 H II region;<sup>51</sup> higher resolution near-infrared observations reveal a cluster with one dominating source (see Figure 2), which likely has the largest contribution to the emission at longer wavelengths. Multiple mm continuum sources are detected toward all the other fields. The N113 B3 field is particularly interesting since it harbors sources at different evolutionary stages, including a hot core and ultracompact H II regions with younger sources distributed along a dense gas filament (see Figures 9 and ref 12). Several mm continuum sources, including one associated with the brightest CH<sub>3</sub>OH peaks in the region, are also found along the filament in N159W-S (see Figures 4 and 5 and ref 76).

The detection of cold methanol in N159W-S and IRAS 01042-7215 P2/P3 is puzzling; however, similar results are being obtained in our Galaxy. In Galactic dark clouds, gas-phase methanol is found to have a clumpy distribution, often not following the density distribution traced by continuum and molecular tracers,<sup>161</sup> and thus provides evidence of rapid ice desorption processes. This methanol tends to be cold, at excitation temperatures of 5–20 K, similar to what is observed in N159W-S and IRAS 01042-7215. In the Barnard 5 cloud in particular, a cold methanol clump with the CH<sub>3</sub>OH abundance with respect to H<sub>2</sub> of ~4 × 10<sup>-8</sup>, offset from the IRAS sources, has proven to be a signpost of ice desorption—by the detection of first cold gas-phase water at abundances similar to that found in methanol<sup>162</sup> and then other COMs like CH<sub>3</sub>CHO and HCOOCH<sub>3</sub>, likely formed by gas-phase chemistry following an

<sup>*a*</sup>The table uses the CDMS notation from the Splatalogue. See footnotes to Table 1 for details. <sup>*b*</sup>The symbols in these columns indicate a detection (+), a tentative detection (+?), or a non-detection (-) of a given molecular line transition; <sup>*c*</sup>The four transitions at ~96.7 GHz are blended; the spectral resolution of these observations, which were dedicated to the continuum detection, is ~50 km s<sup>-1</sup>. In addition to hot cores A1 and B3, there are several other ~96.7 GHz CH<sub>3</sub>OH peaks in N113 (see section 4.3). <sup>*d*</sup>The two methanol peaks associated with MMS-3 where the largest number of CH<sub>3</sub>OH lines are detected and the temperature fitting is the most reliable (see section 4.2.1). <sup>*e*</sup>The CH<sub>3</sub>OH lines at 241.904152 and 241.904645 GHz are blended.

ice desorption event.<sup>102</sup> However, the low yield of COMs from ice desorption at cold temperatures is at most a few percent of methanol even at Galactic metallicities, thus consistent with non-detections of COMs toward N159W-S, IRAS 01042-7215 P2 and P3.

For IRAS 01042-7215, where the  $CH_3OH$  emission is detected toward two sources corresponding to the continuum peak, the authors of ref 19 discussed three possibilities for the nature of P2/P3 (their "east core") where cold methanol was

detected: they suggested it can be either a massive starless core, an embedded high-mass YSO (or multiple YSOs) before the emergence of infrared emission, or a cluster of low-mass embedded YSOs.

Observations confirm that COMs can form in extragalactic environments. Formation pathways have been suggested that involve either grain—surface chemistry or gas-phase chemistry, or a combination of both. Theoretical models accounting for the physical conditions and metallicity of hot molecular cores in the Magellanic Clouds have been able to broadly account for the existing observations.

As cosmic metallicity is increasing with time, understanding interstellar chemistry in low metallicity environments also gives us insight into the chemistry of the past universe. The detection of COMs in the Magellanic Clouds has important implications for astrobiology. The metallicity of the LMC/SMC is similar to the mean metallicity of the interstellar medium during the epoch of peak star formation in the universe, thus the presence of COMs in these systems indicates that a similar prebiotic chemistry leading to the emergence of life, as it happened on Earth, is possible in low-metallicity systems in earlier epochs of the universe. According to one of the theories on the emergence of life on Earth, interstellar COMs (after incorporating into comets) might have been delivered to early Earth to provide important ingredients for the origin of life (e.g., refs 1, 89, and 163).

COMs more complex than  $CH_3OH$  are detected in the LMC toward hot cores which are associated with massive stars and therefore are short-lived; a detection of COMs does not have a direct relation to the origin of life at these locations. However, if COMs are detected toward hot cores, we can expect them to be present in hot corinos, which are associated with low-mass stars. The evolution of low-mass stars is long enough for life to emerge if favorable conditions exist.

#### 7. FUTURE PROSPECTS

Systematic studies on YSOs in different environments in the LMC and SMC are needed to build a statistically significant sample of sources with COMs detections in the Magellanic Clouds that would allow us to draw reliable conclusions on the formation and evolution of COMs in reduced metallicity environments. Both the LMC and SMC samples will be important to get as wide a range of metallicities as possible. In the SMC, the metallicity is lower than in the LMC (as low as 0.1  $Z_{\odot}$  in the SMC tail where star formation occurs in pockets; e.g., ref 164), and the formation and survival of COMs can be tested in an even harsher environment. Enlarging the sample in both galaxies is important to distinguishing between local environmental conditions in individual clouds and the more global effect of metallicity.

Reliable determination of Magellanic Clouds hot cores' physical and chemical properties and a comparison between the two clouds and the Galaxy are of paramount importance to understand the impact of metallicity on complex organic chemistry. High-resolution and high-sensitivity observations of known hot cores in the Magellanic Clouds as their number starts increasing are a natural next step in reaching this goal. This direction of research involves chemical modeling of hot cores to understand their chemical evolution.

ALMA programs are underway targeting tens of YSOs identified by *Spitzer* and *Herschel*, both specifically designed to search for COMs and those with different science goals, but covering frequency ranges where COMs can be detected

(serendipitous detections as in N113). ALMA's broad spectral windows allow the simultaneous observation of many spectral lines, with the spectral setup covering the most important molecules.

What new COMs await discovery in the Magellanic Clouds? Chemical models of the LMC have not been successful (to within an order of magnitude) in accounting for the observed presence of dimethyl ether in the LMC (see section 5.2.2) and so may not be reliable indicators for new molecules. At present, taking the inventory of well-studied Galactic hot cores may provide the best guidelines for future searches. Molecules that could be expected to be present include acetaldehyde, ethanol, ethyl cyanide, isocyanic acid, and formamide.

NASA's James Webb Space Telescope (JWST; scheduled to launch in 2021) near- (0.6-5.3  $\mu$ m; the Near-InfraRed Spectrograph (NIRSpec) instrument) to mid-infrared (4.9-28.8  $\mu$ m; the Mid-Infrared Instrument (MIRI)) observations will enable studies of the solid-phase material in different Galactic and extragalactic environments. The high sensitivity and angular resolution of JWST will enable detailed studies of hot cores in the Magellanic Clouds on ~0.04 pc scales in the near-infrared, without contamination from the surrounding regions. It will be possible to do an inventory of simple (e.g.,  $H_2O_1 CO_2$ , CO) and complex (CH<sub>3</sub>OH and beyond, including molecules of prebiotic significance) ices in the low-metallicity environments in the Magellanic Clouds. For example, in the 5-8  $\mu$ m range (MIRI), COMs such as ethylene glycol, glycolaldehyde, methyl formate, dimethyl ether (the latter two already detected in N113 A1/B3 in the gas phase with ALMA), and others can be detected.<sup>165</sup> Laboratory experiments are underway predicting which COMs can be detected at shorter wavelengths covered by NIRSpec. Such studies will provide information on differences in the chemical complexity of hot cores in different environments.

# APPENDIX A: TECHNICAL DETAILS ON UNPUBLISHED OBSERVATIONS REPORTED IN THIS PAPER

The ALMA and *VLT*/KMOS data presented in section 4.2.1 for N159W-S have not been published in literature yet. Below we summarize technical details of these observations.

# A.1. ALMA

N159W-S was observed with ALMA (Atacama Large Millimeter/submillimeter Array; ALMA Partnership et al., 2015) during its Cycle 4 in October 2016 as part of project number 2016.1.00308.S. We used the main array (i.e.,12-m antennas) consisting of 40 antennas. The phase center was set to RA  $(J2000) = 05^{h}39^{m}41^{s}$ , Dec  $(J2000) = 69^{\circ}46'11''$ . The ALMA correlator was configured to cover specific frequency ranges within the Band 6 of ALMA. Four broad spectral windows (with a bandwidth of 1875 MHz each) centered at frequencies 242.4, 244.8, 257.85, and 259.7 GHz were tuned at the frequencies of specific molecular transitions of dense gas, shock/hot core tracers (e.g., CS, SO<sub>2</sub>, CH<sub>3</sub>OH, and SiO). The ALMA data were calibrated using the ALMA calibration pipeline available in CASA version 5.5.1. Flux calibration was obtained through observations of the bright quasar J0519-4546. The gains were calibrated by interleaved observations of the quasar J0601-7036. The bandpass response was obtained by observing the bright quasar J0635-7516. After the calibration was applied, the linefree channels of the broad spectral windows were identified and used to create the continuum images. The images were made

# ACS Earth and Space Chemistry

using the CASA task TCLEAN with a robust parameter of Briggs equal to 0.5 as compromise between resolution and sensitivity. The resulting images were restored with a synthesized beam of  $0.22 \times 0.12$ . Sensitivity of 1.4 mJy beam<sup>-1</sup> was achieved in the data cube covering the CH<sub>3</sub>OH lines.

#### A.2. VLT/KMOS

N159W-S was observed with VLT/KMOS (Very Large Telescope/K-band Multi-Object Spectrograph) under program 0101.C-0856(A) using the H+K grating with a spectral resolving power of 2000. The observations were carried out using a standard nod-to-sky procedure with an integration time of 150 s, four DITs, and three dither positions, yielding a total on-source integration time of 1800 s. Telluric absorption correction, response curve correction, and absolute flux calibration were carried out using observations of telluric standard stars using three IFUs. The data were reduced with the standard VLT/ KMOS pipeline using the ESOREFLEX data reduction package. The K-band continuum image is produced by integrating over a third-order polynomial fit to the data for every spatial pixel (spaxel) over the spectral range 2.028–2.290  $\mu$ m. The Br $\gamma$  and H<sub>2</sub> line emission images are produced by fitting a Gaussian profile to the emission lines at every position in the image.
