Abstract— In this work, we analyze high frequency performance of graphene field-effect transistors (GFETs), applying models of drain resistance, carrier velocity and saturation velocity. This allows us to identify main limitations and propose an approach most promising for further development of the GFETs suitable for advanced mm-wave amplifiers. Analysis indicates, that the saturation velocity of charge carriers in the GFETs can be increased up to 5·10⁷ cm/s via encapsulating graphene by hexagonal boron nitride layers, with corresponding increase of extrinsic maximum frequency of oscillation up to 180 GHz at 200 nm gate length.

I. INTRODUCTION

Owing to extremely high intrinsic carrier mobility, up to 100 000 cm²/Vs at room temperature, graphene is considered as a promising new channel material in field-effect transistors for advanced mm-wave amplifiers. However, the high frequency performance of the graphene field-effect transistors (GFETs) is limited by a number of intrinsic and extrinsic factors. In particular, the zero-bandgap phenomenon in monolayer graphene results in relatively high drain conductance, which limits the maximum frequency of oscillation (f_max) of the GFETs [1]. Bandgap engineering in graphene is not promising because of simultaneous reduction in the carrier mobility [1]. In this work, we analyze high frequency performance of the GFETs with the high f_max applying models of drain resistance, carrier velocity and saturation velocity. Analysis allows us to identify main limitations and propose most promising approach for further development of the GFETs suitable for mm-wave amplifiers. We show that proper selection of the adjacent dielectric materials with relatively high optical phonon energy can allow for significant increase in the saturation velocity and, hence, f_max of the GFETs.

II. RESULTS

The GFETs have been fabricated in the two-finger gate configuration using high quality, chemical vapor deposited, graphene on oxidized high resistive Si substrates [2]. The technology allows for protection of the top graphene/dielectric interface and, hence, relatively high mobility, up to 2000 cm²/Vs and extremely low contact resistivity, below 100 Ω·μm. This allows for the GFETs operating in the saturation velocity (u_sat) mode, up to u_sat=2·10⁷ cm/s, at intrinsic drain field above 1.5 V/μm. Fig. 1 shows the measured (extrinsic) f_max of the GFETs analyzed in this work together with that of the best previously published GFETs and Si MOSFETs at similar gate lengths (L_g), for comparison [2]. It can be seen, that GFETs in this work reveal record high values of f_max, which are comparable with those of the best reported Si MOSFETs. The lines are simulations using the drain resistance, carrier velocity and saturation velocity models as follows [2,3].

Analytical approximation for the extrinsic f_max derived from the GFET small-signal equivalent circuit is [1]

\[ f_{\text{max}} = \frac{g_m}{4 \pi C_{gs} \left( g_{ds} R_{t} + R_{g} + R_{s} \right) + g_{ds} R_{g} \frac{C_{gd}}{g_{ds}}} \]

where g_m and g_d are the intrinsic transconductance and drain conductance, respectively; C_{gs} and C_{gd} are the gate-source and gate-drain capacitances, respectively; R_g, R_s, and R_t are the gate resistance, source series resistance, and charging resistance of the gate-source capacitance, respectively. We estimated the capacitances as \( C_{gs}=0.5 C_{oX} L_g W_g \) and \( C_{gd}=k C_{oX} \), where \( C_{oX}=3 \cdot 10^{-12} \text{F} \cdot \text{μm}^{-2} \) is the gate oxide capacitance per unit area, \( W_g \) is the gate width and \( k \) is the fitting parameter taking into account the decrease in charge carrier concentration at the drain side [5].

The resistances are estimated as \( R_s=R_t/2 \), where \( R_t \) is total contact resistance, \( R_t=1/(3g_{m0}), R_{t}=R_{sh} W_g/(3L_g) \) and \( R_{sh}=0.08 \Omega \) is the gate electrode sheet resistance [2,6]. We assume that at low fields the Coulomb scattering dominates [7,8]. This allows us to find the \( R_c \) low-field mobility \( (\mu_0) \) and residual carrier concentration \( (\mu_0) \) as parameters via fitting the GFET transfer characteristics by the semi-empirical drain resistance \( (R_{ds}) \) model [2,9]

\[ R_{ds} = R_c + \frac{g_m}{W_g} \frac{1}{n^2 + \left( V_{ds} + V_{dir} \right)} \left( \frac{\varepsilon}{\varepsilon_0} \right)^{1/2} \]

where \( n = \left[ n_0^2 + \left( V_{ds} + V_{dir} \right) \frac{\varepsilon}{\varepsilon_0} \right]^{-1/2} \) is the carrier concentration, \( e \) is the elementary charge, \( V_{ds} \) and \( V_{dir} \) are the gate-source and Dirac voltages, respectively. The intrinsic transconductance is calculated as [2,6]

978-1-5386-8285-2/19/$31.00 ©2019 IEEE
where $u$ is the effective velocity of the charge carriers. It was shown that at the intrinsic drain field $E_{int}(V_{d,s},I_{ds},R_{ds})/I_{ds}$, where $I_{ds}$ is the drain-source current, above approx. 1 V/μm the velocity of the charge carriers in graphene tends to saturate and can be expressed as \[ u = \frac{\mu E_{int}}{1 + \left(\frac{\mu E_{int}}{u_{sat}}\right)^{3/\gamma}} \] where $\gamma=3$ is the fitting parameter for the $u$ dependence on $E_{int}$ found via delay time analysis [10]. We apply the model, which assumes that the saturation velocity is limited by inelastic emission of optical phonons (OPs) and can be approximated as \[ u_{sat} = \frac{2 \omega_{op}}{\sqrt{m}} \sqrt{1 - \frac{\omega_{op}^2}{4m^2 \nu_f^2 N_{F} \nu_F + 1}} \] where $\hbar \omega_{op}$ is the OP energy, the $N_{F}/\hbar \omega_{op}$ is the Fermi velocity and $k_B$ is the Boltzmann constant. We ignore the self-heating effects and assume that the temperature $T=295$ K. Previously we showed, using delay time analysis, that the effective saturation velocity in our GFETs is defined by the combination of the SiO$_2$ surface OPs and the graphene zone-edge OPs with $\hbar \omega_{op}$ = 55 meV and 200 meV, respectively [10]. The lines in Fig. 1 represent calculations using the Eqs. (1)-(5). The upper and lower dotted lines correspond to parameters of the GFETs with highest measured $f_{max}$ (circle) and our previously published GFET (open square), respectively [2,10]. As it can be seen, there is a good agreement with experiments, which validates the used method of simulations combining the models of the drain resistance, carrier velocity and saturation velocity.

Analysis using Eqs. (1)-(5) indicates that $f_{max}$ of the GFETs is limited, mainly, by the relatively high differential drain conductivity, which is caused by the zero energy bandgap in the monolayer graphene [1]. Fig. 2 shows the drain current density $J_{ds}=I_{ds}/W_g$ and corresponding differential drain conductivity $g_{ds-diff}=\partial J_{ds}/\partial E_{int}$ versus $E_{int}$ of the GFET, with $L_g$ = 500 nm and $W_g$ = 30 μm, revealing highest measured $f_{max}$ ~ 37 GHz. It can be seen, that at $E_{int}$=1.7 V/μm, corresponding to the highest $f_{max}$, $g_{ds-diff}$=0.3 mS. For demonstration of the limiting effect of the drain conductance, the solid line in Fig. 1 shows the $f_{max}$, simulated using Eqs. (1)-(5) and the same GFET parameters, but assuming $g_{ds-diff}$=0.01 mS, which is typical for the Si MOSFETs [4]. It can be seen that $f_{max}$ can be up to 300 GHz at $L_g$=200 nm. Approaches of decreasing $g_{ds}$ via inducing a bandgap in graphene are, apparently, not promising because of simultaneous reduction in the carrier mobility and, hence, high-field velocity [1]. Our analysis indicates that a more favorable way is a selection of the adjacent dielectric materials with optical phonon energy higher than that of the SiO$_2$. This will increase the saturation velocity limited by the remote phonon scattering [3,10]. The dashed and dash-dotted lines in Fig. 1 represent $f_{max}$ simulated using Eqs. (1)-(5) and the same GFET parameters, including $g_{ds-diff}$=0.3 mS, but with graphene encapsulated by Al$_2$O$_3$ and hexagonal boron nitride (hBN) layers, respectively. The Al$_2$O$_3$ and hBN optical phonon energy are 87 and 100 meV, respectively, resulting in corresponding saturation velocity of approx. 3-10$^7$ and 5-10$^7$ cm/s [10]. It can be seen that the $f_{max}$ of the Al$_2$O$_3$ and hBN encapsulated GFETs can be approx. 120 and 180 GHz, respectively, at $L_g$=200 nm.

### III. SUMMARY

In this work, we analyzed performance of the GFETs with high extrinsic $f_{max}$=37 GHz, at $L_g$=500 nm, using method of simulations combining the models of the drain resistance, carrier velocity and saturation velocity. It is shown, that the $f_{max}$ is limited, mainly, by the relatively high differential drain conductivity of 0.3 mS, which is approx. 30 times higher than that typical for the Si MOSFETs. A promising approach of further development of the GFETs, suitable for the mm-wave amplifiers, is a selection of the adjacent dielectric materials with optical phonon energy higher than that of the SiO$_2$, resulting in higher saturation velocity. According to the analysis, $f_{max}$ of the Al$_2$O$_3$ and hBN encapsulated GFETs can be up to 120 GHz and 180 GHz, respectively, at $L_g$=200 nm.
