## HIGHLIGHTS

- Manganese oxide nano-catalysts are fabricated by  $\gamma$ -radiation induced method.
- Morphology and composition of MnOx are tuned by the synthesis conditions.
- Oxygen reduction reaction (ORR) activity of the obtained material is studied.
- Hollow spherical  $\gamma$ -MnO<sub>2</sub> particles exhibit a 4-electron transfer pathway.
- Mn<sub>3</sub>O<sub>4</sub> (with composition 2MnO-MnO<sub>2</sub>) nanorods favour an incomplete 2-electron pathway.

## ABSTRACT

A  $\gamma$ -radiation induced synthesis method is used to fabricate manganese oxide catalysts through both reduction and oxidation routes. It is shown that the morphology, composition and electrochemical performance of the produced manganese oxide particles can be tuned by altering the redox conditions. The catalysts prepared *via* radiolytic oxidation have a hollow spherical morphology, possess  $\gamma$ -MnO<sub>2</sub> structure and show high catalytic activity for the complete four-electron reaction pathway of the oxygen reduction reaction (ORR) in alkaline electrolyte. Meanwhile, the catalysts synthesized *via* radiolytic reduction possess a rod-like morphology with a Mn<sub>3</sub>O<sub>4</sub> bulk structure and favour the incomplete two-electron reaction pathway for ORR. The high catalytic activity of the manganese oxide synthesized *via* the oxidation route can be attributed to high electrochemical surface area and increased amount of Mn<sup>3+</sup> on the surface as compared to those in the sample obtained *via* the reduction route.

## 1. Introduction

Manganese oxides are known for their multiple applications for energy storage and conversion [1–4]. In particular, nanostructured MnO<sub>2</sub> has shown considerable catalytic activity for ORR [5–7]. The electrochemical behaviour of manganese oxide is mainly determined by their structural and surface properties [8]. The basic structural unit of MnO<sub>2</sub> is [MnO<sub>6</sub>] octahedrons linked in different ways by sharing edges or corners, thus forming variations in structures [9,10], such as one-dimensional tunnel structure like  $\alpha$ -,  $\beta$ - and  $\gamma$ -MnO<sub>2</sub>, two-dimensional layered structure like  $\delta$ -MnO<sub>2</sub> and three-dimensional spinel structure like  $\lambda$ -MnO<sub>2</sub> [3,11–13]. In earlier studies it was shown that catalytic activity of manganese oxide was dependent on their polymorphs and morphology, where ORR catalytic performance was displayed in the following sequence:  $\alpha$ -MnO<sub>2</sub> >  $\delta$ -MnO<sub>2</sub> >  $\gamma$ -MnO<sub>2</sub> >  $\beta$ -MnO<sub>2</sub> [6,14,15]. Meanwhile,  $\alpha$ -MnO<sub>2</sub> and  $\beta$ -MnO<sub>2</sub> nanowires showed higher catalytic activities as compared to  $\alpha$ -MnO<sub>2</sub> and  $\beta$ -MnO<sub>2</sub> nano-rods [16].

The good electrochemical activity of manganese oxides can be attributed to the redox couple of Mn<sup>3+</sup>/Mn<sup>4+</sup> that exists in the octahedral sites with the presence of vacancies in solid phase [8]. The oxygen reduction on a manganese oxide cathode proceeds through chemical oxidation of surface Mn<sup>3+</sup> ions generated by the discharge of MnO<sub>2</sub> [14] and the total reaction pathway follows a four-electron reduction pathway [17]. In Mn-based compounds, Mn<sup>3+</sup> ions cause one of the largest Jahn-Teller lattice distortions, whereas Mn<sup>4+</sup> ion does not contribute much to those distortions [18]. Furthermore, the ability to transfer electrons from Mn<sup>3+</sup> to the adsorbed oxygen (O<sub>2(ad)</sub>) to form Mn<sup>4+</sup>-O<sub>2(ad)</sub> is an important characteristic of the Mn-based catalysts for ORR [19]. Therefore, the electro-catalytic activity for ORR of different types of Mn oxides can be dependent on the amount of accessible Mn<sup>3+</sup> species on the surface [15].

The ORR performance can be improved by incorporating nanocatalysts on a carbon support that possess high surface area and good conductivity [20,21]. In addition, the synergetic effect can lead to a substantial electron transfer between the supported manganese oxides and carbon, thereby effectively increase the catalytic performance of manganese oxides [22]. The size control and mono-dispersity of nanoparticles has become the main issue and direction in carbon supported nanocomposite fabrication [23,24]. It was shown previously that the structural properties of manganese oxides can be tuned by choosing appropriate synthesis routes [10]. The nanostructured manganese oxides for catalysis applications can be synthesized by for example, sol-gel method [25], co-precipitation method [26], hydrothermal methods [5,15,27,28], wet chemistry methods [11,29], and radiation induced synthesis method [30–32].

During the last decades,  $\gamma$ -radiation induced synthesis of nano-materials attracted significant attention due to the following advantages: low energy consumption; minimal use of potentially harmful chemicals; relatively simple synthesis schemes [33].  $\gamma$ -radiation induced synthesis involves redox reactions between products of water radiolysis, radicals and active species, and dissolved metal salt precursors, resulting in precipitation of less soluble reaction products. Since the formation of the radicals stops immediately when the solution is removed from the radioactive source, the amount of reacting radicals and, thus, the amount of obtained precipitate can be controlled by the total radiation dose with high accuracy. As reported in the literature, by varying  $\gamma$ -radiation induced synthesis parameters, such as radiation dose rate, total dose, scavenger concentration, and type of solvents, nanoparticles with different composition, size and morphology can be engineered. Thus, free-standing MnO<sub>2</sub> nano-wires can be

produced by  $\gamma$ -radiation induced synthesis method via both reductive route, Mn<sup>7+</sup> → Mn<sup>4+</sup>, from KMnO<sub>4</sub> precursor solution, and oxidative route, Mn<sup>2+</sup> → Mn<sup>4+</sup>, from Mn (II) salts solutions [31,34–36].

In the current study we apply  $\gamma$ -radiation induced approach to synthesize not only free-standing MnO<sub>x</sub> nanomaterials but manganese oxide based nanocatalysts deposited on a carbon support, aiming to substantiate how morphology, composition and catalytic activity of the obtained material can be tuned by the redox conditions. The nanocatalysts are synthesized by using different radiolytic routes: oxidation and reduction. Structural properties of the obtained material and its electrochemical activities for the ORR in alkaline electrolyte were investigated.

## 2. Experimental

### 2.1. Radiation induced synthesis of manganese oxide

Radiation induced preparation of metal oxide particles in aqueous solution involves reactions between water radiolysis products and the metal precursor ions. When absorbing ionizing radiation water molecules decompose to form free radicals and molecular species [37]:

Both oxidizing and reducing species are formed in equivalent amounts. The hydrated electron, e<sub>aq</sub><sup>-</sup>, with E<sup>0</sup> (H<sub>2</sub>O/e<sub>aq</sub><sup>-</sup>) = -2.87 V<sub>SHE</sub> can reduce most metal ions to lower valence states [38]. Meanwhile, the hydroxyl radical, OH<sup>•</sup>, is a powerful oxidant, with E<sup>0</sup> (OH<sup>•</sup>/H<sub>2</sub>O) = +1.8 V<sub>SHE</sub> capable to oxidize most metal ions into higher valence state [39]. For radiation induced synthesis, the solution redox condition can be shifted to either reducing or oxidizing conditions by adding the proper radical scavenger before radiation.

Under reducing conditions, OH<sup>•</sup> radicals are scavenged by isopropanol to produce reducing 2-hydroxyl-2-propyl radical (CH<sub>3</sub>)<sub>2</sub>COH<sup>•</sup>, E<sup>0</sup> = -1.8 V<sub>SHE</sub> [40], according to the reaction:

The interaction of precursor KMnO<sub>4</sub> with reducing radicals, e<sub>aq</sub><sup>-</sup> and (CH<sub>3</sub>)<sub>2</sub>COH<sup>•</sup> can be described by the following reactions:

In oxidizing conditions, N<sub>2</sub>O is used to convert e<sub>aq</sub><sup>-</sup> to OH<sup>•</sup> according to the following reaction:

The formation of MnO<sub>2</sub> colloids by the reaction of OH<sup>•</sup> with Mn<sup>2+</sup> ions in solution was described previously [36]. When dissolved in water, Mn<sup>2+</sup> ions form a hydrated species [Mn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>. The formation of MnO<sub>2</sub> can be described by the following overall processes:

Note that in both synthesis paths, pH of the solutions after irradiation is usually decreased from almost neutral to acidic (pH 2 to 3) which is attributed to the formation of H<sup>+</sup> via reactions (4) and (6).

Considering the above, manganese ions in oxidation states Mn<sup>4+</sup> (MnO<sub>2</sub>), Mn<sup>3+</sup> and Mn<sup>2+</sup> can be formed. Note that one needs 3 reducing species to get one molecule MnO<sub>2</sub> and 4.3 reducing species to get an oxide with mixed valences, such as Mn<sub>3</sub>O<sub>4</sub>.

Although the solubility of many  $\text{Mn}^{2+}$  compounds/salts is high,  $\text{Mn}_3\text{O}_4$  is stable in aqueous solutions [41]. The structure of  $\text{Mn}_3\text{O}_4$  may have several modifications, such as  $\text{MnO-Mn}_2\text{O}_3$  (with  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$ ) and  $2\text{MnO-MnO}_2$  (with  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$ ) [42].

## 2.2. Synthesis condition

Manganese oxide particles both free-standing and on carbon support were obtained by  $\gamma$ -radiation induced synthesis using oxidation and reduction routes. In the oxidation route,  $\text{Mn}^{2+}$  salt, manganese chloride tetrahydrate,  $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ , (Sigma Aldrich,  $\geq 99.9\%$  purity) was used as a precursor, while in the reduction route,  $\text{Mn}^{7+}$  salt,  $\text{KMnO}_4$  (Sigma Aldrich,  $\geq 99\%$  purity) was chosen. 5 mM manganese salt precursors concentration was used to synthesize free-standing nanoparticles. Meanwhile, higher salt concentration is required for carbon supported manganese oxide. Carbon powder (Vulcan XC-72, Cabot Carbon Corporation, USA) with a concentration of 2.2 g/L was used as support material and dispersed in the precursor solution by ultrasonic bath for 30 min before radiation.

In the oxidation route, the sample solution was purged with  $\text{N}_2\text{O}$  for 30 min to reach  $\text{N}_2\text{O}$  saturation in water ( $\sim 2.5 \times 10^{-2}$  M) at room temperature. In the reduction route, 1 M isopropanol was added to the sample solution and with  $\text{N}_2$  gas purging for 30 min to remove oxygen from the solution.

The prepared samples were sealed and subjected for irradiation in a gamma-cell (MDS Norditon 1000 Elite Cs-137) with a dose rate of  $0.124 \text{ Gy s}^{-1}$ . After irradiation, the samples were filtered and washed with Milli-Q water. Thereafter, the samples containing carbon support were placed into a furnace, dried at  $60^\circ\text{C}$  in air for 24 h.

The synthesis parameters for  $\gamma$ -radiation induced fabrication of manganese oxide particles both free-standing and on carbon support are summarized in Table 1.

The free-standing manganese oxides produced via reduction and oxidation routes are denoted as  $\text{MnO}_x\text{-Red}$  and  $\text{MnO}_x\text{-Oxi}$ , respectively, whereas, carbon black supported samples are denoted as  $\text{MnO}_x\text{-Red/C}$  and  $\text{MnO}_x\text{-Oxi/C}$  in Table 1.

A number of samples were synthesized. However we chose to describe four samples which are typical representatives of the  $\text{MnO}_x$  samples obtained via radiolytic reduction and oxidation routes. (see Table 1). The influence of other synthesis parameters, such as precursor types ( $\text{MnSO}_4$ ,  $\text{MnCl}_2$ ), concentration, total irradiation dose and solution pH (from 1.5 to 4.5), on  $\text{MnO}_x$  structure and its physical properties were studied. The results are shown in Supplementary Information. It was found that those parameters have less significant contribution to  $\text{MnO}_x$  properties alteration as compared to that caused by the changing redox conditions.

## 2.3. Characterization of structural and chemical composition

Powder X-ray diffraction (XRD) patterns of obtained samples were recorded by a PANalytical X'Pert PRO diffraction system with  $\text{Cu K}\alpha$  radiation ( $\lambda = 1.5418 \text{ \AA}$ ) in a Bragg-Brentano geometry. The angular ( $2\theta$ ) range of  $15^\circ$  to  $90^\circ$  with a step of  $0.01^\circ$  was used.

The morphologies of the samples were investigated by transmission electron microscopy (TEM) operated at 200 kV using

JEOL2100F and Hitachi S-4800 scanning electron microscope (SEM) at a voltage of 15 kV.

The mass loading (wt. %) of manganese on carbon was measured with ICP-OES (Inductively Coupled Plasma-Optical Emission Spectroscopy) method by a Thermo scientific iCAP 600 series instrument. Prior to ICP-OES measurements, 0.2 g of dry powder of each sample was immersed into 20 ml of 5%  $\text{HNO}_3$  with high speed stirring for 24 h. The analysis of Mn was performed at wavelengths of 279 nm and 285.2 nm.

The oxidation states of Mn were analysed using X-ray photoelectron spectroscopy (XPS). For the  $\text{MnO}_x\text{-Red}$  samples, XPS spectra were recorded with a Kratos Axis Ultra electron spectrometer with a delay line detector. A monochromatic  $\text{Al K}\alpha$  source operated at 150 W and a charge neutralizer was used for the measurements. The chamber pressure was below  $3 \times 10^{-9}$  Torr. For the  $\text{MnO}_x\text{-Oxi}$  samples, XPS spectra were recorded with a PerkinElmer PHI 5000C ESCA system. A monochromatic  $\text{Al K}\alpha$  (1486.7 eV) source operated at 50 W and a charge neutralizer was used for the XPS measurements. The chamber pressure was kept below  $6 \times 10^{-10}$  Torr. The concentric hemispherical analyzer was positioned at a  $45^\circ$  angle with respect to the sample normal. The binding energy (BE) scale was referenced to the C 1s of adventitious carbon, set at 284.8 eV. Processing of the spectra was accomplished with Kratos software using Gaussian and Lorentzian functions in the ratio of 70% to 30%. A Shirley background was applied. The element detection limit was typically 0.1 at%.

## 2.4. Electrochemical characterization.

Rotating disc electrode (RDE) measurements were performed to evaluate the ORR activity and carried out on mirror polished glassy carbon electrodes with a geometric area of  $0.196 \text{ cm}^2$ . The electrodes were modified by drop casting specific volumes of catalyst ink and then dried naturally in ambient environment. The details of the ink preparation and electrode modification were described in supplementary information.

All electrochemical measurements were performed in a three-electrode system using a potentiostat (Bio-Logic SP-300) with a graphite rod as a counter electrode and an  $\text{Ag/AgCl}$  in saturated KCl solution as a reference electrode. All the potentials reported here were iR-corrected (85% automatic iR compensation) and calibrated to reversible hydrogen electrode (RHE) according to  $E(\text{RHE}) = E(\text{Ag/AgCl}) + 0.964 \text{ V}$  in 0.1 M KOH.

The electrochemical active surface area (ECSA) of the catalysts was estimated by double-layer capacitance ( $C_{dl}$ ) measurements, according to the method reported in the literature [43]. The double layer charging current ( $i_c$ ) was obtained from CVs at multiple scan rates ( $\nu$ ) at 0.4 V, which was in the potential region where the presence of faradaic currents was minimized and the total current dominated by capacitive currents. By plotting  $i_c$  as a function of  $\nu$ , the slope of the linear fit was equal to  $C_{dl}$  ( $i_c = \nu C_{dl}$ ). The ECSA of the catalyst was calculated by dividing  $C_{dl}$  by  $0.040 \text{ mF cm}^{-2}$ , a typical value reported for Mn electrode in alkaline aqueous solution [43,44]. It should be noted that the calculated ECSA only provides an approximate guide, and since the carbon support also contributes to the capacity, it will represent an overestimation. The electron transfer number ( $n$ ) was calculated using the

**Table 1**

Radiation induced-synthesis parameters: precursor and scavenger type, total irradiation dose, mass loading of Mn on carbon.

Sample	Precursor	Scavenger	Total irradiation dose	Mn mass loading
$\text{MnO}_x\text{-Red}$	5 mM $\text{KMnO}_4$	1 M isopropanol	8.9 kGy	
$\text{MnO}_x\text{-Red/C}$	15.4 mM $\text{KMnO}_4$	1 M isopropanol	44.6 kGy	5.7 wt%
$\text{MnO}_x\text{-Oxi}$	5 mM $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$	$\sim 2.5 \times 10^{-2}$ M $\text{N}_2\text{O}$	8.9 kGy	
$\text{MnO}_x\text{-Oxi/C}$	18 mM $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$	$\sim 2.5 \times 10^{-2}$ M $\text{N}_2\text{O}$	44.6 kGy	21 wt%

Koutecky-Levich (K-L) equation. The detailed description is given in the [supplementary information](#).

### 3. Results and discussions

#### 3.1. Composition, structure, and morphology of manganese oxide catalysts

##### 3.1.1. XPS studies

The elemental composition of the manganese oxide particles deposited on carbon was acquired by XPS. Mn 2p and 3s spectra are shown in [Fig. 1](#) and the corresponding binding energies are presented in [Table 2](#). As shown in [Fig. 1](#) (a) and [Table 2](#), three binding energies for Mn 2p<sub>3/2</sub> are distinguished in both samples. Those energies correspond to different oxidation states of manganese: Mn<sup>3+</sup> [45], Mn<sup>2+</sup> [45–47] and Mn<sup>4+</sup> [42,45,48]. The ratio of O1s to Mn 2p<sub>3/2</sub> of the two samples are close to 1.2, thus, MnO<sub>2</sub> can be one of the oxides present in both samples [49]. Other oxides, especially mixed valence oxides are more difficult to identify. For example, spinel Mn<sub>3</sub>O<sub>4</sub>, [Mn<sup>2+</sup>Mn<sub>2</sub><sup>3+</sup>O<sub>4</sub><sup>2-</sup>] has a structure where Mn<sup>2+</sup> ions are in tetrahedral and Mn<sup>3+</sup> ions are in octahedral sites [50]. This crystal system can undergo spontaneous symmetry breaking that leads to several structures such as MnO-Mn<sub>2</sub>O<sub>3</sub> (Mn<sup>2+</sup> and Mn<sup>3+</sup>) and even 2MnO-MnO<sub>2</sub> (Mn<sup>2+</sup>, Mn<sup>4+</sup>) with a weak interaction between different ion sites can exist for Mn<sub>3</sub>O<sub>4</sub> compound [42]. As reported in the literature, the difference in binding energies of Mn 2p<sub>1/2</sub> and Mn 2p<sub>3/2</sub> levels in the XPS spectrum for mixed oxides can be larger than that for a simple oxide [51]. In our case the spin-orbit splitting between Mn 2p<sub>1/2</sub> and Mn 2p<sub>3/2</sub> levels is 11.6 eV and 11.3 eV for MnO<sub>x</sub>-Oxi/C and MnO<sub>x</sub>-Red/C, respectively, which matches to the values for Mn<sub>3</sub>O<sub>4</sub> [42,49,51]. Therefore, we can assume that manganese oxides with a mixed valence states can be present in both the studied samples.

To further estimate the average Mn valence state in the obtained oxides, we consider binding energies of Mn 3s core-shell. The 3s line for the 3d transition metals has a splitting that depends on the number of 3d electrons [52]. Thus, one can determine the valence state of Mn ions considering the splitting magnitude of Mn 3s line as shown in [Fig. 2](#) (b). The measured splitting of Mn 3s lines of 4.7 eV for both samples correspond to Mn<sup>3.6+</sup> [53].

As shown in [Table 2](#), the surface atomic ratio of Mn species in MnO<sub>x</sub>-Oxi/C is higher than that in MnO<sub>x</sub>-Red/C. Moreover, the Mn<sup>3+</sup>/Mn<sup>4+</sup> ratio in MnO<sub>x</sub>-Oxi/C and MnO<sub>x</sub>-Red/C samples calculated from XPS spectra, is 2.01 and 1.56, respectively. Since, as shown in the literature, ORR activity of different types of manganese oxide is dependent on the amount of Mn<sup>3+</sup> on the surface due to Jahn-Teller distortion effects and the ease oxidation to Mn<sup>4+</sup>, the ratio of Mn<sup>3+</sup>/Mn<sup>4+</sup> may be considered as an important

parameter for the evaluation of the catalytic efficiency of manganese compounds [54].

The XPS studies demonstrate that the materials produced by  $\gamma$ -radiation induced synthesis *via* both oxidation and reducing routes consist of a mixture of solid manganese oxides having Mn ions in a 2+, 3+ and 4+ oxidation state.

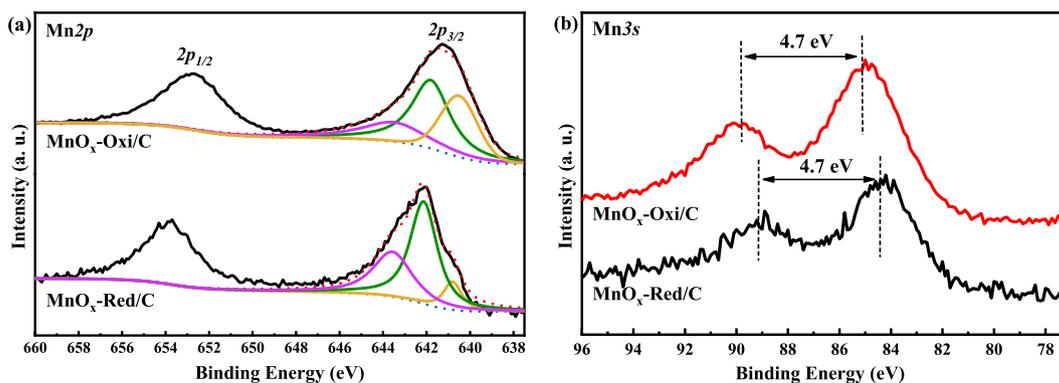

##### 3.1.2. XRD and electron microscopy studies

XRD and electron microscopy studies were performed to further elucidate the composition and structure of the synthesized material. XRD patterns for manganese oxide particles synthesized *via* oxidation and reduction routes are presented in [Fig. 2](#) (a) and (c), respectively. The patterns were recorded from both free-standing and carbon supported particles.

The XRD patterns for the manganese oxide obtained by radiolytic oxidation are shown in [Fig. 2](#) (a). The peaks denoted with Miller indices correspond to  $\gamma$ -MnO<sub>2</sub> phase (JCPDS 14-0644) [16,55]. This phase is constructed of [MnO<sub>6</sub>] octahedral units, arranged in (1 × 2) and (1 × 1) tunnels [9]. As reported in the literature [16,55], the metastable  $\gamma$ -MnO<sub>2</sub> can transform to  $\alpha$ -MnO<sub>2</sub> *via* increasing the reaction temperature or altering solution pH. As also seen in [Fig. 1](#)(a) the diffraction peak from carbon (at  $2\theta$  of about 25°) is almost negligible. This is probably due to the fact that Mn mass loading in MnO<sub>x</sub>-Oxi/C sample is rather high (21 wt%), therefore, the intensity of diffraction peaks from amorphous carbon is dampened by the signal from MnO<sub>x</sub>.

The morphology of  $\gamma$ -MnO<sub>2</sub> particles studied using SEM is shown in [Fig. 2](#)(b). As shown in the figure, the particles have a spherical shape composed of nanoflakes and possess a well-developed surface. The complex morphology of the obtained manganese oxide particles may indicate that their formation in solutions occurred *via* a non-classical crystallization pathway, when the crystallization occurs *via* the formation of a sequence of phases, from emulsion *via* amorphous phases to crystalline intermediates [56,57]. Although the XRD study indicates  $\gamma$ -MnO<sub>2</sub> is the only phase that formed during radiolytic oxidation, the XPS measurements reveal that Mn<sup>2+</sup> and Mn<sup>3+</sup> are also present in the samples. Hence, we assume  $\gamma$ -MnO<sub>2</sub> is a bulk crystalline phase, and meanwhile, contains amorphous phases of both Mn<sup>2+</sup> and Mn<sup>3+</sup> to be formed on the surface.

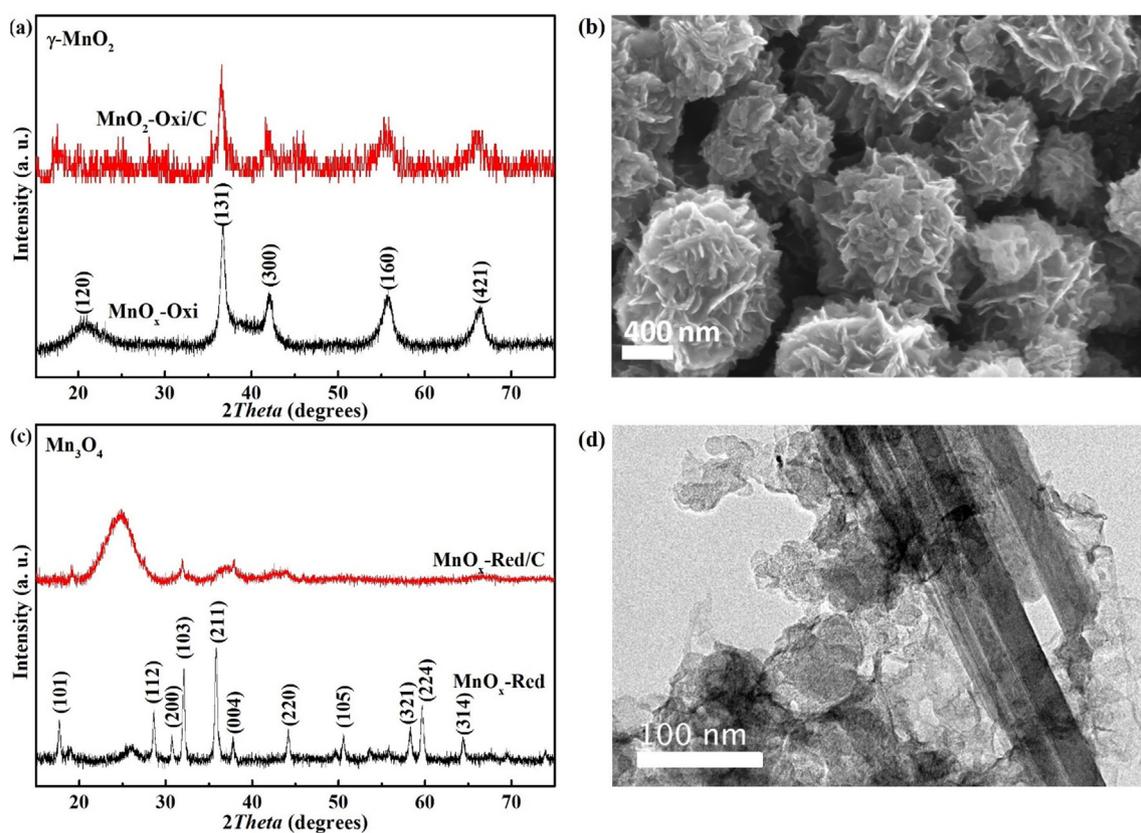

The manganese oxides synthesized by radiolytic reduction possess quite different structure and morphology as compared to that synthesized by radiolytic oxidation. As seen in [Fig. 2](#)(c), the XRD patterns for MnO<sub>x</sub>-Red consist of the peaks, which belong to the tetragonal spinel-type Mn<sub>3</sub>O<sub>4</sub> phase (JCPDS 24-0734) [44,58]. Essentially, these peaks belong to spinel which occurs in nature as the mineral hausmannite, where manganese exists in two oxidation states Mn<sup>2+</sup> and Mn<sup>3+</sup> (MnO-Mn<sub>2</sub>O<sub>3</sub>). However, as shown in the literature, another distorted structure of Mn<sub>3</sub>O<sub>4</sub>,

**Fig. 1.** Mn 2p (a) and Mn 3s (b) XPS spectra of carbon supported manganese oxide particles synthesized by both radiolytic oxidation (upper curves) and radiolytic reduction (lower curves) routes.

**Table 2**  
Results of XPS studies of carbon supported manganese oxides synthesized by both radiolytic oxidation and radiolytic reduction.

Line (compound)	MnO <sub>x</sub> -Oxi/C		MnO <sub>x</sub> -Red/C	
	Binding Energy (eV)	Atomic ratio (at. %)	Binding Energy (eV)	Atomic ratio (at. %)
C 1 s (C–C)	284.8	81.45	284.3	92.53
O 1 s (Mn–O)	529.1	6.9	529.8	2.3
O 1 s (C=O, Mn–OH)	530.8	3.45	531.1	0.8
O 1 s (C–OH)	532.5	1.85	532.1	1.1
O 1 s (C–OH)			533.3	0.75
O 1 s (H <sub>2</sub> O)			535.1	0.28
Mn 2p <sub>3/2</sub> (Mn <sup>3+</sup> )	641.9	2.98	642.1	0.78
Mn 2p <sub>3/2</sub> (Mn <sup>2+</sup> )	640.5	1.89	640.8	0.14
Mn 2p <sub>3/2</sub> (Mn <sup>4+</sup> )	643.5	1.48	643.6	0.49
Mn 2p <sub>1/2</sub>	652.7		652.0	

**Fig. 2.** X-ray diffraction patterns of free-standing manganese oxide particles and on a Vulcan X-72 synthesized by radiolytic oxidation (a); and radiolytic reduction (c). The wide XRD peaks at  $2\theta \sim 25^\circ$  correspond to amorphous carbon; SEM image of manganese oxide particles synthesized by radiolytic oxidation (b); TEM image of manganese oxide nano-rods synthesized by radiolytic reduction (d).

$2\text{MnO}-\text{MnO}_2$  with  $\text{Mn}^{2+}$  and  $\text{Mn}^{4+}$  can coexist [42]. Considering the results from the XPS study that shows the presence of  $\text{Mn}^{4+}$  together with  $\text{Mn}^{2+}$  ( $\text{Mn}^{3+}$ ) at the surface, we expect that the composition of the samples obtained by the reduction route would rather correspond to  $2\text{MnO}-\text{MnO}_2$  than to  $\text{MnO}-\text{Mn}_2\text{O}_3$ .

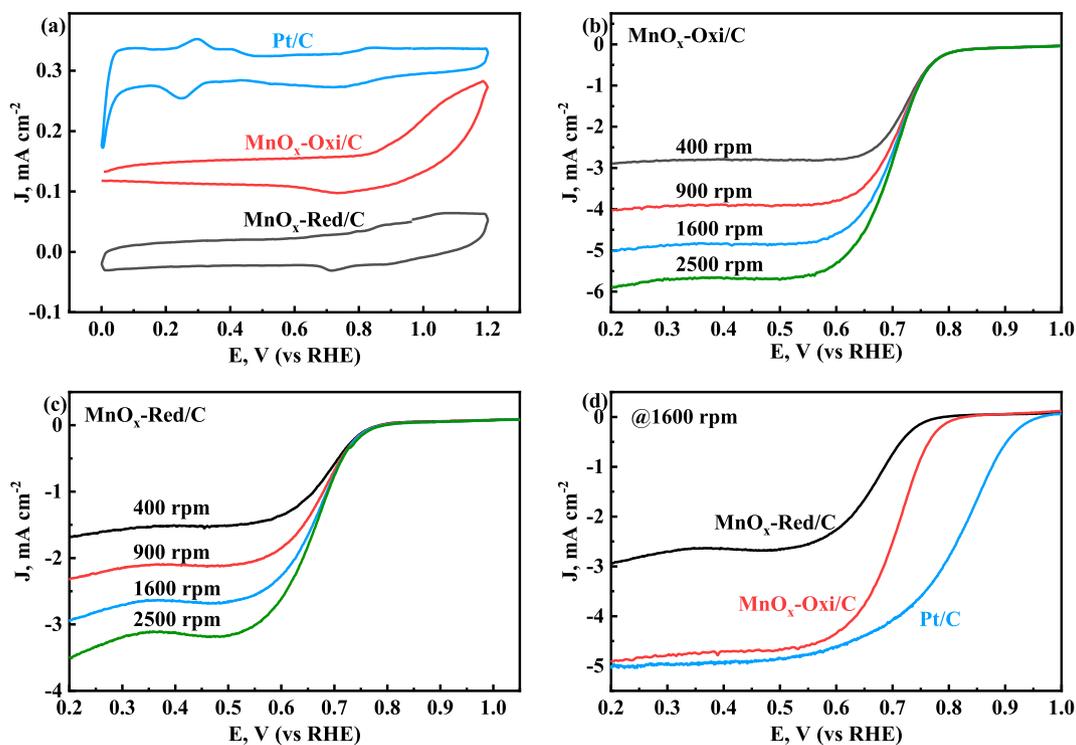

The morphology and the surface structure of the catalyst produced via the reduction route were characterized using TEM and shown in Fig. 2(d). Apart from the samples obtained by radiolytic oxidation, the sample synthesized via the reduction route consists of a mixture of nano-rods and nanowires. The amorphous carbon with “onion” structure is clearly seen in the image.

### 3.2. Electrochemical characterization

#### 3.2.1. Electrocatalytic activity measured by RDE

The ORR measurements were performed in 0.1 M KOH with a rotating disk electrode (RDE) setup. Cyclic voltammetry (CV) of

synthesized carbon supported manganese oxide catalysts and commercial Pt/C (20 wt%, ETEK) were obtained at a scan rate of  $50 \text{ mV s}^{-1}$  (Fig. 3(a)). The CV curves of  $\text{MnO}_x\text{-Red/C}$  and  $\text{MnO}_x\text{-Oxi/C}$  samples showed reduction peaks at potentials around 0.7 V and oxidation peaks around 1.05 V, which was consistent with the result in literature [59]. Pt/C showed the standard CV curve with characteristic shape of polycrystalline Pt in alkaline medium [60]. The ORR kinetics of the carbon supported manganese oxide catalysts was investigated by collecting polarization curves at various rotation speeds (Fig. 3(b) and (c)). For all the samples, the higher rotation speed will give faster oxygen diffusion, thus resulting in higher diffusion limiting current density ( $J_d$ ). Table 3 summarizes the key parameters for ORR performance obtained from the polarization curves. It can be seen that, the  $J_d$  of  $\text{MnO}_x\text{-Oxi/C}$  almost reached the value of Pt/C ( $5.0 \text{ mA cm}^{-2}$ ) and much higher than that of  $\text{MnO}_x\text{-Red/C}$  ( $2.8 \text{ mA cm}^{-2}$ ). Both of the onset potential  $E_{\text{onset}}$  and half-wave potential  $E_{1/2}$  of synthesized carbon supported

**Fig. 3.** Cyclic Voltammograms recorded for  $\text{MnO}_x\text{-Oxi/C}$ ,  $\text{MnO}_x\text{-Red/C}$  and commercial Pt/C (20%) catalysts in  $\text{N}_2$  saturated 0.1 M KOH solution with the scan rate at  $50 \text{ mV s}^{-1}$  (a). Polarization curves at different rotation rates measured on manganese oxide catalysts synthesized by oxidation (b) and reduction (c) routes. Polarization curves of  $\text{MnO}_x\text{-Oxi/C}$ ,  $\text{MnO}_x\text{-Red/C}$  and Pt/C at the rotation speed of 1600 rpm (d). All the polarization curves in Fig. 3(b)–(d) were recorded at the scan rate of  $10 \text{ mV s}^{-1}$ . (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

**Table 3**

ORR performance parameters obtained from polarization curves shown in Fig. 3(d). Electron transfer number was calculated from K-L plots in Fig. 4 (a).

Sample	$J_d$ ( $\text{mA cm}^{-2}$ )	Electron transfer number	$E_{\text{onset}}$ (V)	$E_{1/2}$ (V)	Specific Activity @ 0.7 V ( $\text{mA cm}^{-2}$ )
$\text{MnO}_x\text{-Oxi/C}$	4.8	4.1	0.8	0.71	0.03
$\text{MnO}_x\text{-Red/C}$	2.8	2.6	0.76	0.66	0.02
Pt/C	5	4.0	0.94	0.82	0.91

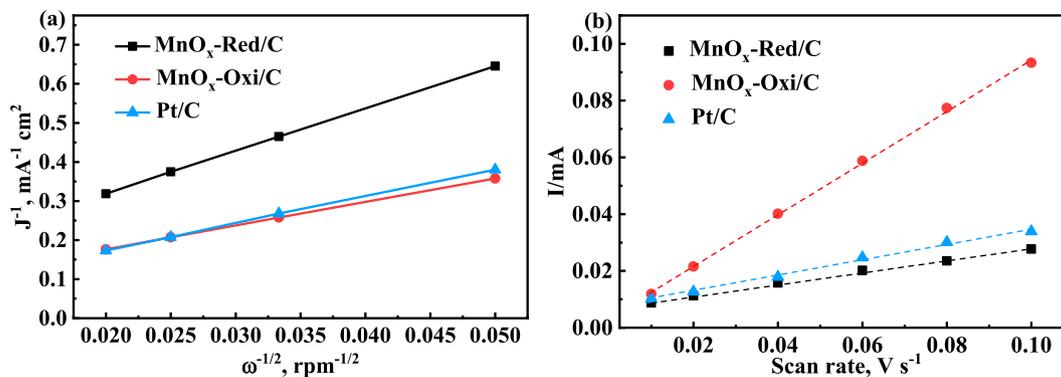

manganese oxide catalysts were lower than Pt/C, but it can be clearly seen that the potentials of  $\text{MnO}_x\text{-Oxi/C}$  were much more positive than that of  $\text{MnO}_x\text{-Red/C}$ , which indicates a higher ORR activity of the  $\text{MnO}_x\text{-Oxi/C}$  sample at low overpotentials. The  $E_{1/2}$  of Pt/C sample showed a little negative shift comparing with the value in some other studies but it should be noted that all the ORR parameters of Pt/C were within the range that have been reported in literatures where the similar recipe of catalyst ink and conditions of measurement were applied [61–63]. To investigate the first order ORR kinetics, the electron transfer number ( $n$ ) was determined by K-L plots ((Fig. 4(a)). The calculated electron transfer number of  $\text{MnO}_x\text{-Red/C}$  sample was 2.6, whereas, the  $n$  value for  $\text{MnO}_x\text{-Oxi/C}$  and Pt/C were 4.0 and 4.1, respectively, demonstrating a four-electron oxygen reduction pathway and the high electro-catalytic activity towards ORR. This matches very well with the fact that the diffusion limited current of sample  $\text{MnO}_x\text{-Red/C}$  was about half of sample  $\text{MnO}_x\text{-Oxi/C}$ .

To eliminate the effect of a carbon support, the ORR activity for both  $\text{MnO}_x\text{-Oxi/C}$  and  $\text{MnO}_x\text{-Red/C}$  catalysts having similar Mn loading, was investigated. Therefore, a  $\text{MnO}_x\text{-Red/C}$  sample that contains 21 wt% of Mn was prepared, and its ORR activity was compared to the activity of the other samples. The results are shown in Fig. S3. As seen in the figure the overall ORR activity of  $\text{MnO}_x\text{-red/C}$  catalysts only slightly increases when concentration of Mn in the

sample is increased by 3.7 times (from 5.7 wt% to 21 wt%). Still this activity remains significantly smaller than the ORR activity of a  $\text{MnO}_x\text{-Oxi/C}$  sample. Dissimilarity in the samples' morphology, nano-rods and hollow spheres in  $\text{MnO}_x\text{-red/C}$  and  $\text{MnO}_x\text{-Oxi/C}$  samples, respectively, can be a possible reason for the difference in the electrochemical performance of the  $\text{MnO}_x$  catalysts

### 3.2.2. Electrochemical active surface area of the $\text{MnO}_x/\text{C}$ catalysts

The electrochemical active surface area (ECSA) measurement provides information on the number of electrochemically active sites on the electrode which directly relates to the sample's electrocatalytic activity [64,65]. In the current work, the ECSA of the catalysts was estimated by analysing the double-layer capacitance and the actual amount of metal on GC electrode which was determined by ICP-OES after electrochemical test. Fig. 4(b) shows the plot of capacitive currents as a function of the scan rate with the corresponding linear fits. The capacitive currents were obtained from the CVs in the non-Faraday region, which are presented in Fig. S1. Table S1 lists the double-layer capacitance ( $C_{dl}$ ) and ECSA value of  $\text{MnO}_x\text{-Oxi/C}$  and  $\text{MnO}_x\text{-Red/C}$  samples, respectively. The ECSA of sample  $\text{MnO}_x\text{-Oxi/C}$  ( $113.9 \text{ m}^2 \text{ g}_{\text{Mn}}^{-1}$ ) is twice as large as that of  $\text{MnO}_x\text{-Red/C}$  ( $52.3 \text{ m}^2 \text{ g}_{\text{Mn}}^{-1}$ ), which can be attributed to the high porosity and large surface area, mainly owing to the accumulation of nanoflakes on its surface and, thus, results in an overall

**Fig. 4.** K – L plots calculated for MnO<sub>x</sub>-Oxi/C, MnO<sub>x</sub>-Red/C and commercial Pt/C electrodes at 0.4 V (vs RHE),  $J$  is a current density,  $\omega$  is a rotation rate of a disk electrode (a). Capacitive current as a function of the scan rate with corresponding linear fits to the experimental data (b). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

three-dimensional hierarchical nanostructure. The ECSA of Pt/C calculated from  $C_{dl}$  is  $171.2 \text{ m}^2/\text{g}_{\text{Pt}}$ , which is larger than what has been previously reported [66,67], indicating the fact that the double-layer capacitance method may not be a suitable technique to determine the ECSA of Pt/C sample. Therefore, the ECSA was recalculated at  $43.1 \text{ m}^2/\text{g}_{\text{Pt}}$  based on the modified  $H_{\text{upd}}$  method [68], and the value is within the range reported in literatures [62,63,66]. Specific activity of the catalysts has been calculated from the ECSA and listed in Table 3. As seen in the table the specific activity of both MnO<sub>x</sub>/C samples is much lower than that of Pt/C, which is expected. However, MnO<sub>x</sub>-Oxi/C sample showed higher specific activity than MnO<sub>x</sub>-Red/C, which could be ascribed to the difference in samples morphology and composition. The way to improve the specific activity of manganese based catalysts can include reducing the size of the active compounds down to a level of a single atom, as well as using different supports such as, for example, nitrogen-doped carbon, to create active interfacial sites [69,70]. Although this is beyond the scope of the current study, it can be a topic for future investigations.

The results of stability tests performed on both types of catalysts in O<sub>2</sub> saturated 0.1 M KOH solution are shown in Fig. 5. As seen in the figure both MnO<sub>x</sub>/C samples exhibited good electrochemical stability. The current density of MnO<sub>x</sub>-Oxi/C showed a decrease from the initial value  $1.48 \text{ mA cm}^{-2}$  to  $1.40 \text{ mA cm}^{-2}$  after

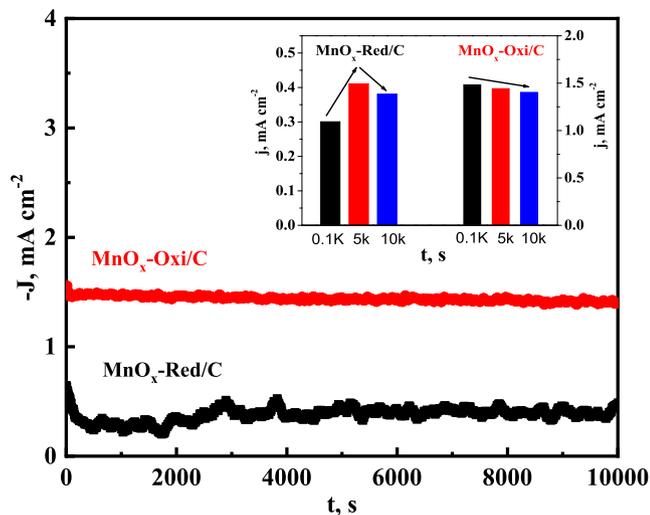

10000 s of the experiment run at 0.7 V (5.4% decay). Also, the current density of MnO<sub>x</sub>-Red/C had a minor increase (from  $0.30 \text{ mA cm}^{-2}$  in initial to  $0.41$  after 5000 s) followed by a small decrease (ended at  $0.38 \text{ mA cm}^{-2}$  after 10000 s). Good stability of MnO<sub>x</sub>/C samples may be attributed to the special morphology of the catalyst which can keep the overall structure and composition from further transformation, and thus, the active sites could be then maintained to a great extent. Small fluctuations of current density in MnO<sub>x</sub>-Red/C sample could be due to possible de-adhesion of the neighbor nanorods, thus exposing more active sites and resulting in increasing current density.

#### 4. Conclusions

In this study we demonstrated that by varying redox condition of a precursor solution in the  $\gamma$ -radiation induced synthesis one can tune the morphology, composition and electrochemical performance of manganese oxide catalysts. Manganese oxide nanoparticles both free standing and on carbon support were synthesized by  $\gamma$ -radiation induced synthesis method. Both radiolytic oxidation and reduction were used. The samples prepared via the oxidation route possess a hollow spherical shape composed of nanoflakes, which structure corresponds to that of  $\gamma$ -MnO<sub>2</sub>. Meanwhile, the samples produced via the reduction route possess a rod-like morphology and have Mn<sub>3</sub>O<sub>4</sub> (probably 2MnO-MnO<sub>2</sub>) as the main crystalline phase. The ORR activities of the obtained catalysts were controlled by RDE measurements. It was found that samples synthesized via radiolytic oxidation exhibit a 4-electron pathway, while an indirect 2-electron pathway was observed in the samples obtained via radiolytic reduction. High ORR activity of the MnO<sub>x</sub>-Oxi/C sample can be attributed to its high electrochemical surface area originating from the three-dimensional hierarchical nanostructure. Moreover, as confirmed by the XPS analysis, the surface concentration of Mn<sup>3+</sup> in the MnO<sub>x</sub>-Oxi/C sample is larger than that in the MnO<sub>x</sub>-Red/C sample, which may contribute to the increased electro-catalytic activity of the former. In addition, both types of catalysts demonstrated good electrochemical stability in alkaline solutions. Thus, the  $\gamma$ -radiation induced synthesis method can be applied as a structural and composition adjustable approach to fabricate manganese oxide electro-catalyst with improved ORR activity and stability.
