Abstract—In this paper, we present a low-latency direction-assisted channel estimation algorithm suitable for millimeter wave (mm-Wave) systems. First, during the beam training procedure, we perform angle of departure (AoD) and angle of arrival (AoA) measurements with their corresponding variances and based on them, we design both downlink and uplink beams. We then perform signal measurements with these beams and accordingly design the sensing matrix, while also iteratively refining the angle estimation and the beams for the next measurements accordingly. Finally, exploiting both the sparseness and the intrinsic geometric nature of the mm-Wave channel, we apply compressive sensing tools so as to complete the estimation procedure. Simulations show that the corresponding estimation error decreases rapidly in comparison with other conventional approaches.

I. INTRODUCTION

The millimeter wave (mm-Wave) technology has been touted as a strong contender to accommodate the rapidly burgeoning demands for both data traffic and throughput in the new fifth generation (5G) of cellular systems [1]. The motive behind this choice is clear: operating in the millimeter wave (mm-Wave) band (typically, at a central frequency $>24$ GHz) offers a huge amount of unlicensed bandwidth, and hence, the opportunity to multiplex high data rates among multiple users at the same time. Moving up the mm-Wave spectrum does not come without complications, however. The propagation characteristics of radio signals at such high frequencies proves to be a serious impediment to the advantages mentioned above. These signals are indeed affected by severe power pathloss, additional propagation losses due to specific environmental conditions (e.g., rain, fog) and even more importantly, radio blockages [2], [3].

On the other hand, transmitting signals of shorter wavelengths like in mm-Wave allows for smaller antenna sizes [4]. Exploiting this reduced size, instead of using only one antenna, a large number of antenna elements can thus be integrated on both sides of the radio link to concentrate the signal power in specific directions of space and overcome signal attenuation, what is also known as beamforming [5]. One major challenge of mm-Wave beamforming (and beyond, of beam alignment) is that the transmitter needs to have a fairly good knowledge of channel information with respect to the receiver so as to transmit the beam with the adequate width in the right direction. In this demanding context, channel estimation is thus of the highest importance.

In the literature, this mm-Wave channel estimation problem has been addressed from the perspective of two distinct stages, namely the beam training stage and the estimation algorithm stage. Firstly, for the beam training stage, the most straightforward approach is to exhaustively search the best beams in terms of received power, by testing all possible angular directions on both transmitter’s and receiver’s sides [6]. In contrast, [7] and [8] propose iterative multi-resolution beam training procedures, where larger beams are used first, before converging iteratively to a beam width corresponding to the a priori required spatial resolution. Likewise [9] proposes a similar iterative beam training process in presence of prior location information fed by angle of departure (AoD) and angle of arrival (AoA), significantly reducing the estimation latency. In [10], the authors devise a channel estimation strategy employing distinct beam patterns in different directions. The latter two strategies reduce the channel estimation duration, which is critical in case of 5G applications due to their both low latency requirements and the necessity to operate at mm-Wave, possibly under mobility. Secondly, in the estimation stage, most of the contributions are based on compressive sensing techniques, exploiting the aforementioned sparsity of the channel, with algorithms such as orthogonal matching pursuit (OMP) [11]–[13], simultaneous orthogonal matching pursuit (SOMP) [14] and L1-norm minimization [15].

In this paper, we mainly consider the beam training stage and study how directional information, in particular, angular measurements can be used to further assist channel estimation. Our main motivation is to minimize the number of searches (and hence the duration) performed by the transmitter and the receiver beam pair in the conventional methods. Due to the sparse and geometric nature of the mm-Wave channel, the exploitation of such angular information is indeed expected to be beneficial to estimation, especially in terms of latency.

II. SYSTEM MODEL

A. Deployment scenario

Consider a mm-Wave downlink scenario with a base station (BS) and a user, equipped respectively with $N_t$ antennas and
scatterers, as illustrated in Fig. 1. The BS, the user and the k-th scatterer are located at positions $q = [q_x, q_y]^T$, $p = [p_x, p_y]^T$ and $s_k = [s_{k,x}, s_{k,y}]^T$ respectively. The position of the BS is assumed to be known, whereas that of both user and the scatterers are unknown a priori. The BS is assumed to have a known orientation, whereas the user is arbitrarily oriented towards an angle $\theta \in (0, 2\pi]$ with respect to the reference $x$-axis (as indicated in the figure).

### B. Channel model

The $N_r \times N_t$ complex channel matrix between the BS and the user is denoted by $H$ and is formulated as in [8].

$$H = \sqrt{\frac{N_r N_t}{\rho}} \sum_{k=0}^{K} h_k e^{-j2\pi k \rho} a_{R_k}(\phi_k) a_{T_k}^H(\theta_k), \quad (1)$$

where $\rho$ is the average path-loss term, $h_k$, $\tau_k = d_k/c$ (with $c$, the speed of light), $\theta_k$ and $\phi_k$ are respectively the complex channel coefficient, the time delay, the AoD and the AoA of the $k$-th path between the BS and the user, $T_s = 1/B$ is the sampling period, $a_{T_k}(\theta_k) \in \mathbb{C}^{N_t}$ and $a_{R_k}(\phi_k) \in \mathbb{C}^{N_r}$ are the antenna array response vectors at the BS and the user respectively. Similarly to [14], we can define

$$\begin{align*}
\theta_k &= \begin{cases} 
\arccos \left( \frac{p_x-q_x}{\|p-q\|^2} \right) & k = 0 \\
\arccos \left( \frac{s_{k,x}-q_x}{\|s_{k}-q\|^2} \right) & \text{otherwise},
\end{cases} \quad (2a) \\
\phi_k &= \begin{cases} 
\pi + \arccos \left( \frac{p_x-q_x}{\|p-q\|^2} \right) - \theta \quad k = 0 \\
\arccos \left( \frac{p_x-q_x}{\|p-q\|^2} \right) - \phi 
\end{cases} \quad (2b)
\end{align*}$$

Considering a uniform linear array (ULA) model for the antenna array, we can express $a_{T_k}(\theta_k)$ as

$$a_{T_k}(\theta_k) = \frac{1}{\sqrt{N_t}} \left[1, e^{j\frac{\pi d}{\lambda} \cos(\theta_k)}, \ldots, e^{j(N_t-1)\frac{\pi d}{\lambda} \cos(\theta_k)} \right]^T. \quad (3)$$

where $d$ is the distance between two antenna elements. Similarly, we can formulate $a_{R_k}(\phi_k)$ by replacing $N_t$ with $N_r$ and $\theta_k$ with $\phi_k$ in equation (3).

We can reformulate equation (1) similarly to [8] as

$$H = \sqrt{\frac{N_r N_t}{\rho}} A_{R_k} A_{T_k}^H, \quad (4)$$

where,

$$A_{T_k} = [a_{T_k}(\theta_0), \ldots, a_{T_k}(\theta_K)], \quad (5a)$$

$$A_{R_k} = [a_{R_k}(\phi_0), \ldots, a_{R_k}(\phi_K)], \quad (5b)$$

$$\Lambda = \text{diag} \left( h_0 e^{-j2\pi q_0}, \ldots, h_K e^{-j2\pi q_K} \right). \quad (5c)$$

### C. Communication model

Consider a downlink scenario between the BS and the user. If the BS uses a beamforming vector $f_p$, and the mobile device uses a combining vector $w_q$, the resulting received signal can be written as:

$$y_{q,p} = w_q^H H f_p s_p + n_{q,p}, \quad (6)$$

where, $s_p$ is the transmitted symbol such that $E\left[ s_p^2 \right] = P_{T_x}$, where $P_{T_x}$ is the average power used per transmission, and $n_{q,p}$ is a Gaussian distributed noise with zero mean and bilateral power spectrum density $N_0/2$ per real dimension. Considering $M_B$ and $M_T$ of such beamforming and combining vectors respectively, the received signal can be written as

$$Y = WHHFS + N, \quad (7)$$

where $W = [w_1, w_2, \ldots, w_M]$ and $F = [f_1, f_2, \ldots, f_M]$. Similarly to [8], for the channel estimation phase, we assume all the transmitted symbols are equal i.e. $S = \sqrt{T_s} I_{M_B}$, where $I$ is an identity matrix of size $M_B$, and hence

$$Y = \sqrt{P_{T_x}} W H F + N. \quad (8)$$

### D. AoD and AoA estimation

We assume that the BS and the user have access to an estimator of the AoD ($\hat{\theta}_k$) and AoA ($\hat{\phi}_k$) respectively for every path. Hence, for the $k$-th path, the estimated AoD and AoA can be expressed as:

$$\hat{\theta}_k = \theta_k + \epsilon_{\theta_k}, \quad (9a)$$

$$\hat{\phi}_k = \phi_k + \epsilon_{\phi_k}, \quad (9b)$$

where, $\epsilon_{\theta_k}$ and $\epsilon_{\phi_k}$ are the estimation errors regarding $\theta_k$ and $\phi_k$ respectively. It was shown in [18] that under conditions such as a large number of transmit and receive antennas and a non-ideal channel, the AoD and AoA can be estimated with high resolution due to the large number of antenna elements [17].
large bandwidth, which is reasonable in mm-Wave, the error for both AoD and AoA can be assumed as independent per path. Moreover, we assume that the random measurement noise terms are Gaussian distributed with zero mean and known variances\(^2\) \(\sigma_\eta^2\) and \(\sigma_\phi^2\) [19].

III. DIRECTION AIDED CHANNEL ESTIMATION

The objective of channel estimation is to estimate the matrix \(H\) in a multipath scenario. Equivalently, one can estimate the channel coefficient and the three location dependent variables (i.e., delay, AoD and AoA) for each path. In this section, we firstly express the channel estimation problem as a sparse problem. We then introduce the sectorized beamforming model to simplify the previous channel estimation problem. Finally, we propose the direction aided channel estimation algorithm.

A. Channel estimation problem

Vectorizing equation (8), we can write

\[
y_v = \text{vec}(Y) = \sqrt{P_y} \text{vec}(W^H H F) + \text{vec}(N), \quad (10a)\]

\[
\zeta \left( F^T \otimes W^H (A_{Tx} \otimes A_{Rx}) \text{vec}(A) + n_v \right)
\]

\[
\zeta \left( F^T A_{Tx}^* \otimes W^H A_{Rx} \right) x + n_v, \quad (10c)
\]

where \(\zeta = \sqrt{N_y N_f P_y / \rho}\), \(x = \text{vec}(A)\) and \(n_v = \text{vec}(N)\).

In order to present a sparse formulation of the estimation problem, consider a grid of \(N_B\) discrete AoD and \(N_U\) AoA directions taken uniformly between 0 and 2\(\pi\), with the \(i\)-th grid direction represented by \(\theta_i\) and \(\phi_i\) for AoD and AoA respectively. Mathematically, \(\theta_i = 2\pi (i-1)/N_B\) and \(\phi_i = 2\pi (i-1)/N_U\).

\[
A_{Tx} = \begin{bmatrix} a_{Tx}(\theta_1), \ldots, a_{Tx}(\theta_{N_B}) \end{bmatrix}, \quad (11a)
\]

\[
A_{Rx} = \begin{bmatrix} a_{Rx}(\phi_1), \ldots, a_{Rx}(\phi_{N_U}) \end{bmatrix}. \quad (11b)
\]

Similarly to [8, equation (17)], we can now reformulate equation (10c) as a sparse problem:

\[
y_v = \zeta \left( F^T A_{Tx}^* \otimes W^H A_{Rx} \right) x + n_v = \zeta M x + n_v, \quad (12)
\]

where \(M\) is the sensing matrix and the \(k\)-th element in \(y_v\) is

\[
y_k = \zeta \left( f_p^T A_{Tx}^* \otimes w_q^H A_{Rx} \right) x + n_k = \zeta M(k,:) x + n_k, \quad (13)
\]

where the \(k\)-th measurement is performed with the beamforming vector \(f_p\) and the combining vector \(w_q\), and \(M(k,:)\) represents the \(k\)-th row of the sensing matrix. Likewise

\[
f_p^T A_{Tx} = \begin{bmatrix} a_{Tx}^H(\theta_1) f_p, \ldots, a_{Tx}^H(\theta_{N_B}) f_p \end{bmatrix}, \quad (14a)
\]

\[
w_q^H A_{Rx} = \begin{bmatrix} w_q^H a_{Rx}(\phi_1), \ldots, w_q^H a_{Rx}(\phi_{N_U}) \end{bmatrix}. \quad (14b)
\]

Equation (14a) (and equivalently, equation (14b)) represents the gain due to the beamforming vector \(f_p\) in all the grid directions. Hence, \(f_p^T A_{Tx}^* \otimes w_q^H A_{Rx}\) represents the gain due to \(f_p\) and \(w_q\) in all the BS and user grid combinations (\(N_B \times N_U\) combinations).

B. Sectorized beamforming model

We approximate the actual beamforming by a sectorized model [20], where the transmitted and received beams are divided into two sectors, a main lobe sector whose antenna gain depends on the beamwidth \(\omega\) and a side lobe sector with a fixed gain. The beamwidth is inversely proportional to the number of antenna elements.

Accordingly, in the sectorized model, the antenna gain \(G_x(\omega_x)\), where \(x \in \{\text{Tx, Rx}\}\) at the BS side i.e. \(f^H A_{Tx}(\theta_k)\) and user side i.e. \(w^H A_{Rx}(\phi_k)\) can be estimated similarly to [8], [21]

\[
G_x(\omega_x) = \begin{cases} \gamma_x(\omega_x) G_0 \frac{2 \pi - (2 \pi - \omega_x) \epsilon}{\omega_x}, & \text{in the main lobe,} \\ g = G_0 \epsilon, & \text{otherwise,} \end{cases} \quad (15)
\]

where \(G_0\) is the antenna gain of an equivalent omni-directional beam (i.e., \(\omega_x = 2 \pi\)) and \(\epsilon\) is a small positive constant \(\ll 1\).

C. Sensing matrix design

From equations (13) and (15), each element of the sensing matrix \(M\) in (12) can have four distinct values: \(\gamma_{Tx}(\omega_{Rx})\gamma_{Rx}(\omega_{Rx})\), \(\gamma_{Tx}(\omega_{Rx})g\gamma_{Rx}(\omega_{Rx})\) and \(g^2\) depending on the beam alignment and beamwidths.

Consider an example scenario as illustrated in Fig. 2 with a BS, a user and two paths: a direct path and an indirect path through \(s_1\). The complex channel coefficient of direct path \(h_0\) is indicated by \(\alpha_0\) and that of indirect path \(h_1\) is \(\alpha_1\). Consider equi-spaced grids at both BS and user with \(N_B = N_U = 8\) with \(\theta_i = \phi_i = 2\pi (i-1)/8\) for all natural numbers \(i \leq 8\).

We have beams from the BS and the user with widths \(\omega_{Tx}\) and \(\omega_{Rx}\) respectively, both directed at a scatterer located at \(s_1\). Let \(m_{BS} = f^T A_{Tx}^*\) and \(m_{MS} = w^H A_{Rx}\). As illustrated in the figure, only the indirect path is covered by the main lobes of both BS and user side beams. Then, the received signal composed of two paths can be expressed as follows:

\[
y = \zeta \left[ \sum_{k=0}^{1} G_{Rx}(\omega_{Rx,k}) G_{Tx}(\omega_{Tx,k}) \alpha_k + n, \quad (16a)\right.
\]

\[
= \zeta \left[ \gamma_{Tx}(\omega_{Tx,1}) \gamma_{Rx}(\omega_{Rx,1}) \alpha_1 + g^2 \alpha_0 \right] + n, \quad (16b)
\]

and each row of the sensing matrix for the given beam pair can be calculated as

\[
m_{Tx} = \left[ g, \gamma_{Tx}(\omega_{Tx}), g, g, g, g, g, g \right], \quad (17a)
\]

\[
m_{Rx} = \left[ g, g, g, \gamma_{Rx}(\omega_{Rx}), g, g, g, g \right], \quad (17b)
\]

\[
M(k,:) = m_{Tx} \otimes m_{Rx}. \quad (17c)
\]

D. Beam design

The key to efficiently solving the sparse problem in (12) is to obtain the right measurements. In order to do so, based on the angle estimates from equation (9), for each path, we design the optimal beamwidth \(\omega_{Tx}\) and \(\omega_{Rx}\) at both BS and user respectively in such a way as to minimize the beam
misalignment error per path. We define the misalignment error as the event that the scatterer (or correspondingly the receiving node in case of direct path transmission) doesn’t fall within the main beam lobes of either transmitting or receiving nodes due to estimation errors. This event is depicted in Fig. 3. 

Based on this definition of the misalignment error, we design the beamwidth \( \omega_{Tx,k} \) with respect to the \( k \)-th path such that the probability of misalignment error is a constant \( \epsilon_{Tx} \), i.e.,

\[
P\left( \hat{\theta}_k - \frac{\omega_{Tx,k}}{2} \leq \theta \leq \hat{\theta}_k + \frac{\omega_{Tx,k}}{2} \right) = \epsilon_{Tx}. \tag{18}\]

Accordingly,

\[
\omega_{Tx,k} = 2\Phi^{-1}\left( \frac{\epsilon_{Tx} + 1}{2} \right) \sigma_\theta, \tag{19}\]

where, \( \Phi^{-1}(x) \) is the inverse function of the cumulative distribution function (CDF) of standard normal distribution. Likewise,

\[
\omega_{Rx,k} = 2\Phi^{-1}\left( \frac{\epsilon_{Rx} + 1}{2} \right) \sigma_\phi. \tag{20}\]

In the above equations, we use the relations from equations (9a) and (9b), where \( \hat{\theta}_k \) and \( \hat{\phi}_k \) are normally distributed around the true AoD and AoA for each \( k \)-th path.

4In practice, the ability of an antenna to beamform with a certain width depends on the number and the geometry of the antenna elements. In our scenario, we assume that both BS and user have enough elements to support a small beamwidth. In the context of ULA, the minimum number of antenna elements required to achieve a beamwidth \( \omega \) can be approximated [22, Equation 1.9] as \( 1.8/\omega \). Then to achieve other larger beamwidths, we can select the required number of antenna elements according to the optimization problem formulated in [23, 24].

E. Direction aided channel estimation algorithm

The overall direction aided channel estimation algorithm can be summarized by the following steps.

Output: \( \hat{H} \)

Initialization:
1: Initial estimates of AoD \( \hat{\theta}_k^{(1)} \) and AoA \( \hat{\phi}_k^{(1)} \) at the BS and user respectively for all \((K+1)\) paths and their corresponding variances \( \sigma_{\theta_k}^2 \) and \( \sigma_{\phi_k}^2 \).
2: \( i = 1 \)

Beam Training Phase:
3: \textbf{while} terminating condition\(^5\) is not satisfied \textbf{do}
4: \textbf{for} all \( \hat{\theta}_{k_1}^{(i)} \) and \( \hat{\phi}_{k_2}^{(i)} \) \textbf{pair} \( \forall k_1, k_2 \in \{0, 1, \cdots K\} \) \textbf{do}
5: Calculate the beamwidth \( \omega_{Tx,k_1}^{(i)} \) and \( \omega_{Rx,k_2}^{(i)} \) for BS and user beams according to equations (19) and (20) respectively.
6: Set the BS and user beams towards \( \hat{\theta}_{k_1}^{(i)} \) and \( \hat{\phi}_{k_2}^{(i)} \) respectively with widths \( \omega_{Tx,k_1}^{(i)} \) and \( \omega_{Rx,k_2}^{(i)} \).
7: With these beams, generate the received signal \( y_i \), according to equation (16a).
8: Calculate the corresponding row of the sensing matrix \( M(i,:) \), as in equation (17c).
9: \textbf{if} \( |y_i|^2 \geq \gamma_i \) \textbf{then}
10: With downlink transmission towards \( \hat{\theta}_{k_1}^{(i)} \) with beamwidth \( \omega_{Tx,k_1}^{(i)} \), the BS estimates the refined AoA \( \hat{\phi}_k^{(i+1)} \).
11: With uplink transmission towards \( \hat{\phi}_k^{(i)} \) with beamwidth \( \omega_{Rx,k_1}^{(i)} \), the user estimates the refined AoD \( \hat{\theta}_k^{(i+1)} \).
12: Update the estimation variances \( \sigma_{\theta_k}^2 \) and \( \sigma_{\phi_k}^2 \).
\textbf{end if}
13: \( i = i + 1 \)
14: \textbf{end for}
15: \textbf{end while}

Estimation Algorithm Phase:
17: \( z = \text{OMP}(M, y) \) and reshape \( z \) from \( N_B N_U \times 1 \) vector to a \( N_B \times N_U \) matrix.
\[
\hat{A} = \text{reshape} \left( z, [N_B, N_U] \right). \tag{21}\]
18: \( \hat{H} = \hat{A}_R \hat{A}^H \hat{A}_T \)
19: \textbf{return} \( \hat{H} \)

In summary, we firstly initialize the algorithm with coarse estimates of the AoDs and AoAs along with their variances for all the paths. For each AoD and AoA, we then calculate the beamwidth such that we limit the misalignment error probabilities to \( \epsilon_{Tx} \) and \( \epsilon_{Rx} \) at the transmitter and the receiver respectively. We then sequentially transmit for every pair of AoD and AoA, in total \((K+1)^2\) pairs, with the newly calculated beamwidth and measure the received signal and the corresponding row of the sensing matrix according to equations (16a) and (17c) respectively. Following, we refine

\(^5\)The terminating condition can be application dependent. It can be, for \( e.g. \), the minimum beamwidth constraint, the total channel estimation duration constraint, \( etc. \).
AoDs and AoAs, as well as their corresponding variances, for each path with the new beamwidth. We only perform this step if the BS and user beam pairs are corresponding to either the direct path or the same scatterer, hence \( K + 1 \) times. In order to decide when to perform this step, we threshold the received signal power on \( \gamma_k \), which is a function of \( \omega_{\text{Tx}k1}^{(i)} \) and \( \omega_{\text{Rx}k2}^{(i)} \), such that we only measure the angles when both the main lobes are aligned towards either each another or the same scatterer. This beam refining and measuring process is iteratively repeated until some application dependent terminating condition is fulfilled. The sparsity of mm-Wave channel ensures that the sensing matrix is sparse, and hence we use some compressive sensing algorithm such as OMP [13] in this case to finally estimate the channel.

### IV. Numerical Results

In our work, we assume an analog beamforming architecture on both BS and user sides with only 1 radio-frequency (RF) chain operating at \( f_c = 28 \) GHz with bandwidth \( B = 500 \) MHz. We assume the transmit power \( P_\text{tx} = 30 \) dBm and the noise power density at the received signal \( N_0 = -174 \) dBm. We consider 1 BS with known position \( (q = [0,0]^T) \) and orientation \( (\phi = 0^\circ) \), and \( K = 3 \) scatterers (and accordingly, 4 paths). Moreover, we assume the \( N_B = N_U = 360 \) grid points at both the BS and the user respectively. For determining the beamwidth, we consider \( c_{\text{tx}} = c_{\text{rx}} = 0.99 \).

We compare our proposed direction assisted channel estimation method with that resulting from two well-known solutions, namely exhaustive search and iterative multi-resolution search [6], [8]. For the exhaustive search, we consider the beamwidth of the BS and the user to be fixed and equal to \( \omega_{\text{tx,ex}}^\text{ex} \) and \( \omega_{\text{rx,ex}}^\text{ex} \). Thus, the BS and the user go through all the possible combinations of beams throughout the search area with the width in order to complete the beam training process. On the other hand, for the case of iterative multi-resolution based search, we implement the multipath channel estimation algorithm in [8], where we start with an initial beamwidth of \( \pi/2 \) rad and iteratively bisect the beamwidth and sweep to converge to finer resolution. We assume that each transmission can be completed within 14.3\( \mu \)s which is equal to one orthogonal frequency division multiplexing (OFDM) symbol length [25]. For the case of the proposed direction aided method, we choose the minimum beamwidth constraint at both BS and user’s end as terminating condition for the algorithm i.e. the algorithm terminates when the refined beamwidth reaches 1 degree at both the ends for all different AoDs and AoAs. This minimum beamwidth requirement corresponds to the minimum number of antenna required to obtain 104. With this consideration, we assume \( N_T = N_R = 128 \).

We characterize the error in channel estimation in terms of normalized mean square error (NMSE), defined as \( \text{NMSE} = \frac{||H - \hat{H}||_2^2}{||H||_2^2} \), where, \( ||.||_2 \) represents the 2-norm.

In Fig. 4, we can see the minimum beamwidth that can be achieved within a given duration. For instance, during \( x \) \( \mu \)s, we can transmit \( n = \lfloor x/14.3 \rfloor \) beam pairs. For the case of exhaustive search based channel estimation, since we need to search the entire \( \pi/2 \) space in \( x \) \( \mu \)s, the minimum beamwidth that we can use is \( \omega_{\text{tx}}^\text{ex} = \omega_{\text{rx}}^\text{ex} = \pi/2n \) rad. In case of iterative search, the minimum beamwidth we can achieve during \( n \) steps is given by \( \omega_{\text{tx}}^\text{it} = \omega_{\text{rx}}^\text{it} = \pi/2\log_2(n) \), since the search sector grows to the power of 2 at each bisection. For the direction based method, the minimum beamwidth with \( n \) possible beam pairs depends on how fast the beamwidth converges at each iteration and hence, on the variance of estimated AoD and AoA. Since the previous variances, and thus the beamwidths, vary for each path, for the proposed direction aided method, we plot both the minimum and maximum beamwidths allocated at each iteration. In our simulations, in order to have a closed form expression, we assume Cramer Rao Lower Bound (CRLB) as the angle estimation variance when estimating the AoD and AoA, as derived in [14]. In Fig. 4 we can see that the beamwidth in the proposed direction assisted algorithm decreases much more quickly than in other cases.

In Fig. 5, we also present the NMSE of channel estimation for each method for different channel estimation duration and different total channel estimation duration.

\( ^6 \)Although CRLB represents a lower bound on the variance of an unbiased estimator and hence, the best case scenario, the authors in [14] show that it is possible for an estimator to achieve the bound even at low SNR.
with different beamwidths corresponding to the estimation duration, as shown in Fig. 4. In this figure, we can observe that with the proposed direction aided method, the estimation error, similar to the beamwidth, decreases more rapidly than the other methods. The reason for this is that in the proposed method, we use directly the relevant beams even though there is a small probability of misalignment. However, in the exhaustive and iterative search based methods, a lot of time is spoilt while searching all the sectors including those which do not provide any relevant information. This gain in latency could be crucial especially in the context of low latency 5G applications and in dynamic channel estimation scenarios, for e.g., tracking a mobile user.

V. CONCLUSIONS

In this paper, we have presented a low latency solution for channel estimation in the context of mm-Wave systems, with the aid of direction information. Exploiting the inherently sparse properties of the mm-Wave channel, where the number of multipath components is limited, as well as AoD and AoA estimation for each path, we show that the direction aided method outperforms other existing methods such as the exhaustive and iterative multi-resolution search based channel estimation approaches. Simulation results in a canonical scenario illustrate some latency gains accordingly. In future works, we will consider coupling the proposed mm-Wave multipath channel estimation method with angle-based simultaneous localization and mapping algorithms.
