ABSTRACT

We report new photometric and spectroscopic observations of the K2-99 planetary system. Asteroseismic analysis of the short-cadence light curve from K2's Campaign 17 allows us to refine the stellar properties. We find K2-99 to be significantly smaller than previously thought, with $R_* = 2.55 \pm 0.02 R_\odot$. The new light curve also contains four transits of K2-99 b, which we use to improve our knowledge of the planetary properties. We find the planet to be a non-inflated warm Jupiter, with $R_b = 1.06 \pm 0.01 R_{\text{Jup}}$. 60 new radial velocity measurements from HARPS, HARPS-N, and HIRES enable the determination of the orbital parameters of K2-99 c, which were previously poorly constrained. We find that this outer planet has a minimum mass $M_c \sin i_c = 8.4 \pm 0.2 M_{\text{Jup}}$, and an eccentric orbit ($e_c = 0.210 \pm 0.009$) with a period of 522.2 ± 1.4 d. Upcoming TESS observations in 2022 have a good chance of detecting the transit of this planet, if the mutual inclination between the two planetary orbits is small.

Key words: planetary systems—planets and satellites: detection—planets and satellites: individual: K2-99 b—planets and satellites: individual: K2-99 c.

1 INTRODUCTION

Giant planets found orbiting close to their stars have long been assumed to have formed beyond the snow line, and subsequently migrated towards their star, although *in situ* formation has also been proposed (e.g. Batygin, Bodenheimer & Laughlin 2016; Huang, Wu & Triuid 2016). Two classes of migration mechanism have been proposed to explain the existence of such planets: migration through the protoplanetary disc, and dynamical processes including planet–planet scattering and Lidov–Kozai cycles, where eccentricity and inclination are exchanged periodically. Disc-driven migration (Goldreich & Tremaine 1980; Lin & Papaloizou 1986) is predicted to produce giant planets in circular orbits with low obliquities (i.e. the orbital axis and the axis of stellar rotation are well aligned). Planet–planet scattering (Rasio & Ford 1996; Weidenschilling & Marzari 1996) and migration via Lidov–Kozai cycles (Kozai 1962; Lidov 1962; Eggleton & Kiseleva-Eggleton 2001; Wu & Murray 2003; Fabrycky & Tremaine 2007), however, should lead to highly eccentric orbits, with large obliquities. However, in the case of giant planets in orbits with periods of just a few days (the hot Jupiters), these orbital imprints of dynamical migration can be erased through tidal interactions with the host star. These tidal forces act to reduce the eccentricity and obliquity of the orbit, often on time-scales much shorter than the main-sequence lifetime of the host star.

Due to the strong dependence of these time-scales on the orbital distance ($\tau_e \propto a^{-13/2}$; e.g. Jackson, Greenberg & Barnes 2008), planets orbiting just a little further out than hot Jupiters are thought to retain their primordial (post-migration) eccentricity and obliquity, because the time-scales for circularisation and alignment are longer than the stellar main-sequence lifetime. These warm Jupiters (usually defined as giant planets orbiting at distances greater than 0.1 AU, or with periods longer than 10 d) are intrinsically rarer than hot Jupiters (Wittenmyer et al. 2010; Santerne et al. 2016). They are also substantially more difficult to detect with ground-based, wide-field transit surveys such as WASP (Pollacco et al. 2006) or HAT (Bakos et al. 2004), which are responsible for the majority of hot Jupiter discoveries.

There is growing evidence (Dawson & Johnson 2018 and references therein) that multiple migration mechanisms are required to explain the observed populations of hot and warm Jupiters. The existence of warm Jupiters on eccentric orbits, and with massive outer companions (such as the CoRoT-20 system; Deleuil et al. 2012; Rey et al. 2018) is evidence for high-eccentricity tidal migration, for instance. On the other hand, many warm Jupiters are found to have close planetary companions (Huang et al. 2016), the presence of which is incompatible with high-eccentricity migration. Other systems, such as Kepler-419 (Dawson et al. 2012, 2014) appear to be ideal examples of post-Kozai migration, but have a mutual inclination between planetary orbits that is thought to be too small for Kozai migration to have taken place.

The study of systems containing a warm Jupiter is therefore vital for our understanding of planetary migration, and transiting systems are particularly valuable. Solving the full three-dimensional geometry of warm Jupiter systems with outer companions may prove crucial to understand the role of outer companions in high eccentricity migration.

The discovery of a planet orbiting K2-99 (= EPIC 212803289) was reported in Smith et al. (2017, hereafter ‘Paper I’). K2-99, a subgiant, was observed during K2’s Campaign 6, and found to host a massive ($M_b = 0.97 \pm 0.09 M_{\text{Jup}}$, $R_b = 1.29 \pm 0.05 R_{\text{Jup}}$) transiting planet in an eccentric ($e_b = 0.19 \pm 0.04$) orbit, with a period of 18.25 d. A systemic radial acceleration of $-2.12 \pm 0.04 \text{ ms}^{-1} \text{ d}^{-1}$

gave strong evidence for the presence of a third body in the system. In Paper I, we concluded that this third body was most likely to be a massive planet or brown dwarf orbiting with a period of several hundred days. If this third body has a high mutual inclination with K2-99 b, it could be responsible for the high-eccentricity migration of the inner planet to its current orbit.

The KESPRINT¹ team has continued to monitor the radial velocity (RV) of K2-99, in order to determine the orbit of the outer body. In this paper, we present these RV measurements, along with new photometric observations from K2’s Campaign 17. We describe these new observations in Section 2, and perform a new characterization of the properties of the star, using asteroseismology in Section 3. In Section 4 we perform joint modelling of the transit photometry and radial velocities to determine the parameters of both K2-99 b and K2-99 c. Section 5 describes a search for additional signals in the data, and we discuss the likelihood that the outer planet exhibits transits, and the prospects for observing such transits in Section 6. Finally, we discuss the architecture of the K2-99 system in Section 7, and present our conclusions in Section 8.

2 OBSERVATIONS

2.1 Spectroscopy

2.1.1 HARPS and HARPS-N

We have continued to monitor the RV of K2-99 with spectroscopic observations using the HARPS and HARPS-N instruments. 17 new measurements² were made between 2017 August 18 and 2019 May 23 (UT) with the HARPS spectrograph (Mayor et al. 2003; $\lambda \in (378\text{--}691) \text{ nm}$, $R \approx 115\,000$), mounted on the ESO 3.6-m telescope at La Silla Observatory, Chile. A further 24 measurements³ were made between 2017 April 1 and 2019 March 10 (UT) using HARPS-N ($\lambda \in (378\text{--}691) \text{ nm}$, $R \approx 115\,000$; Cosentino et al. 2012), mounted on the 3.58-m Telescopio Nazionale Galileo (TNG), at the Roque de los Muchachos Observatory on La Palma, Spain.

The exposure times varied from 1800 to 3600 s in the case of HARPS and from 1500 to 4000 s in the case of HARPS-N, depending on weather conditions and scheduling constraints, leading to a signal-to-noise (S/N) per pixel of 25–74 at 550 nm and of 30–87 at 550 nm for HARPS and HARPS-N, respectively. HARPS spectra were extracted using the off-line version HARPS_3.8 of the DRS pipeline and HARPS-N spectra using off-line version HARPN_3.7 of the DRS (Cosentino et al. 2014). In the case of both spectrographs Doppler measurements (absolute RVs) and cross-correlation function (CCF) activity indicators [full width at half-maximum (FWHM) and bisector spans] were measured by cross-correlating the extracted spectra with a G2 mask (Baranne et al. 1996). Based on the prescription provided by Lovis et al. (2011) we also measured Mount Wilson S-index (S_{MW}) using our custom-developed code. In Table B1 we list all of the HARPS and HARPS-N RVs, including those previously reported in Paper I for the sake of completeness.

³Conducted under programmes A33TAC.15, A34TAC.10, OPT17A.64, A35TAC.26, OPT17B.59, CAT17B.99, CAT18A.130, OPT18A.44, A37TAC.37, OPT18B.52, and A38TAC.26.

2.1.2 HIRES

The California Planet Search team took 19 spectra of K2-99 between 2016 June and 2016 August, using the HIRES spectrograph at the W. M. Keck Observatory on Mauna Kea, Hawaii, USA. The RVs were analyzed with an iodine-free high S/N observation (200 at 550 nm) taken with the B3 decker ($0.86 \text{ arcsec} \times 14.0 \text{ arcsec}$), allowing for removal of light from night sky emission lights and reflected moonlight. The observing procedures follow those described in Howard et al. (2010). A median exposure time of 426 s results in spectra with a median S/N of 103 per pixel and an internal uncertainty of 3.6 m s^{-1} . In Table B2 we list the 19 newly-obtained HIRES RVs, as well as those previously obtained from the Tull and FIES instruments, and reported in Paper I.

2.2 K2 Campaign 17

K2-99 was originally observed by the K2 mission, the re-purposing of the *Kepler* satellite to observe in the ecliptic plane (Howell et al. 2014), in Campaign 6 (Paper I). K2's Campaign 17 ran from 2018 March 2 to 2018 May 8, and overlaps significantly the Campaign 6 field, including K2-99. K2-99 was observed as one of 179 short-cadence targets, meaning observations were conducted every minute instead of the usual 30 min for most targets. Four transits of K2-99 b were observed during this campaign.

We started from the pixel-level data downloaded from the *Mikulski Archive for Space Telescopes (MAST)* website. The loss of two reaction wheels degraded the pointing stability of the *Kepler* spacecraft significantly (Howell et al. 2014). The photometric measurements thus suffered from short-term (hours) systematic variations. To mitigate this systematic effect, we employed an approach similar to that of Vanderburg & Johnson (2014). Briefly, we put down a circular aperture of 4 pixel in radius around the brightest pixel in the image. We then computed the centre of light within the aperture after subtracting the background median. We then fitted a spline between the flux summed within the aperture and the position of the centre of light. The detrending was done by dividing the original flux with the best-fitting spline variation. Our pipeline has previously been used to extract short-cadence light curve for other systems observed by K2 (Dai et al. 2017).

3 STELLAR CHARACTERIZATION

3.1 Spectral analysis

We co-added all of the HARPS spectra (from Paper I and the newly-obtained spectra described in Section 2.1 and listed in Table B1). This resulted in a spectrum with a signal-to-noise of around 228, higher than that used in Paper I.

We modelled the stellar effective temperature, $T_{\star, \text{eff}}$, the surface gravity, $\log g_{\star}$, abundances, and line widths with SME (Spectroscopy Made Easy; Valenti & Piskunov 1996; Piskunov & Valenti 2017) version 5.22, a spectral analysis package that fits our co-added HARPS spectra to synthetic spectra for a given set of parameters. We used the Atlas12 (Kurucz 2013) atmosphere grids and extracted the required atomic and molecular line data from VALD (Ryabchikova et al. 2015). We used spectral features sensitive to photospheric parameters such as the broad line wings of $\text{H}\alpha$ that was used to model $T_{\star, \text{eff}}$, the line wings of the Ca $\lambda\lambda 6102, 6122, \text{ and } 6162$ triplet and the Mg Ib $\lambda\lambda 5167, 5172, \text{ and } 5183$ triplet that were used to model $\log g_{\star}$. The abundances of Fe, Mg, and Ca relative to hydrogen, and the projected stellar rotational velocity, $v \sin i_{\star}$, were modelled

from narrow lines between 6200 and 6600 Å. We found $[\text{Ca}/\text{H}] = 0.24 \pm 0.05$, $[\text{Mg}/\text{H}] = 0.25 \pm 0.08$, $[\text{Fe}/\text{H}] = 0.20 \pm 0.05$, and $V \sin i_{\star} = 9.8 \pm 1.0 \text{ km s}^{-1}$. We fixed the macro- and micro-turbulent velocities, V_{mac} and V_{mic} , to 5.8 km s^{-1} (Doyle et al. 2014) and 1.2 km s^{-1} (Bruntt et al. 2010), respectively. Our modelling suggests (by comparing $T_{\star, \text{eff}}$ to the tabulation of Pecaut & Mamajek 2013) that K2-99 is a F9 IV star, with an uncertainty smaller than one subclass. This is a slightly earlier spectral classification than the G0 IV determined in Paper I.

3.2 Spectral energy distribution fit

We used the publicly available software ARIADNE (Vines & Jenkins (in preparation); Acton et al. 2020; Smith et al. 2021) to derive the stellar radius. In brief, ARIADNE analyses the spectral energy distribution (SED) by fitting grids of stellar models to catalogue photometry, constrained by the *Gaia* parallax. The *Gaia* EDR3 G , G_{BP} , and G_{RP} , 2MASS J , H , and K , and *WISE* $W1$ and $W2$, and the Johnson B and V magnitudes from APASS were fitted to the Phoenix v2 (Husser et al. 2013), BtSettl (Allard, Homeier & Freytag 2012), Castelli & Kurucz (2003), and Kurucz (1993) atmospheric model grids. Priors on $T_{\star, \text{eff}}$, $\log g_{\star}$, and $[\text{Fe}/\text{H}]$ were taken from our SME model, and on the parallax from *Gaia* EDR3 ($\theta = 1.93 \pm 0.02 \text{ mas}$). Reddening was accounted for, with A_V limited to the maximum line-of-sight value from the SFD Galactic dust map (Schlegel, Finkbeiner & Davis 1998; Schlafly & Finkbeiner 2011).

The resulting stellar radius, computed with Bayesian Model Averaging, is found to be $2.64 \pm 0.06 R_{\odot}$. Combining this result with the surface gravity, we find a mass of $1.46 \pm 0.15 M_{\odot}$. Note that the high precision of the parameters determined by ARIADNE results from the Bayesian model averaging technique used to derive the uncertainties from the posterior parameter distribution. The distributions for each model are averaged, weighted by the relative probability of each model, leading to smaller uncertainties than those obtained from any single model (Acton et al. 2020).

3.3 Asteroseismology

To perform an asteroseismic analysis, the K2 light curve was first optimized for this purpose. Large outliers were removed following García et al. (2011) and all the gaps were interpolated using a multi-scaled discrete cosine transform following inpainting techniques as described in García et al. (2014) and Pires et al. (2015).

We analysed the power spectral density (PSD) of the asteroseismic optimized light curve in order to determine the global seismic parameters of the solar-like oscillations (see e.g. García & Ballot 2019 for more details). The first seismic parameter is the frequency of maximum oscillation power, ν_{max} , which has been shown to be related to the surface gravity of the star (Brown 1991). The second quantity that we can extract from the PSD is the mean large frequency separation, $\Delta\nu$, which is the distance in frequency between two modes of same degree and consecutive orders. This quantity is proportional to the square root of the mean density of the stars (Kjeldsen & Bedding 1995). Two different methods were used to estimate $\Delta\nu$ and ν_{max} . We first applied the A2Z pipeline (Mathur et al. 2010). The mean large frequency spacing is computed by taking the power spectrum of the power spectrum in boxes of $300 \mu\text{Hz}$ allowing us to also compute thresholds to determine the confidence level of the detection (see Mathur et al. 2010 for more details). The frequency of maximum power comes from the fit of a Gaussian function in the region of the modes after removing the fit of the

convective background using two Harvey laws (Harvey 1985). We detected the modes with more than 95 per cent of confidence level. We obtained $\Delta\nu = 40.35 \pm 0.84 \mu\text{Hz}$ and $\nu_{\text{max}} = 660 \pm 16 \mu\text{Hz}$.

The second method that was applied consists in fitting on the PSD a global p-mode pattern using the APOLLINAIRE⁴ MCMC peakbagging library (Breton et al. 2021). The p-mode pattern equation is adapted from equation (27) from Lund et al. (2017),

$$\nu_{n,\ell} = \left(n + \frac{\ell}{2} + \epsilon \right) \Delta\nu - \delta\nu_{0\ell} - \beta_{0\ell}(n - n_{\text{max}}) + \frac{\alpha}{2}(n - n_{\text{max}})^2, \quad (1)$$

where n and ℓ are the mode order and degree, respectively, ϵ is a phase shift and α the mode curvature. We define $\delta\nu_{0\ell}$ as (see e.g. Corsaro et al. 2012):

$$\begin{aligned} \delta\nu_{00} &= 0, \\ \delta\nu_{01} &= \frac{1}{2}(\nu_{n,1} - \nu_{n+1,0}) - \nu_{n,1}, \\ \delta\nu_{02} &= \nu_{n,0} - \nu_{n,2}, \end{aligned} \quad (2)$$

α and $\beta_{0\ell}$ are the curvature terms on $\Delta\nu$ and $\delta\nu_{0\ell}$, respectively, while n_{max} is given by

$$n_{\text{max}} = \frac{\nu_{\text{max}}}{\Delta\nu} - \epsilon. \quad (3)$$

This second methodology provides $\Delta\nu = 39.98 \pm 0.40 \mu\text{Hz}$ and $\nu_{\text{max}} = 673.13 \pm 18.17 \mu\text{Hz}$, in agreement with the values from the A2Z pipeline.

The MCMC process, implemented with the ensemble sampler of the EMCEE library (Foreman-Mackey et al. 2013) is designed to sample the distribution of parameters θ of the posterior probability,

$$p(\theta|\mathbf{S}_x) = \frac{p(\mathbf{S}_x|\theta)p(\theta)}{p(\mathbf{S}_x)}, \quad (4)$$

where $p(\theta)$ is the parameter prior distribution, $p(\mathbf{S}_x)$ a normalization factor. As the PSD follows a χ^2 with two degrees of freedom (Woodard 1984), $p(\mathbf{S}_x|\theta)$ the likelihood function is given by

$$p(\mathbf{S}_x|\theta) = \prod_{i=1}^k \frac{1}{S(v_i, \theta)} \exp \left[-\frac{S_{x_i}}{S(v_i, \theta)} \right], \quad (5)$$

with S and S_x the ideal and observed spectrum, respectively. The chains are sampled with 500 walkers and 1000 steps. The first 50 steps have been removed in order to correctly take the burn-in phase into account. The final parameters are taken as the median of the sampled distribution (with the burn-in phase correctly taken into account) and their uncertainties as the largest value when considering the differences between the median and the 16th and 84th percentiles of the distribution, respectively.

To characterize the individual oscillation modes, APOLLINAIRE fits a set of single Lorentzian profiles, one per each degree and radial order from $\ell = 2, n = 13$ up to $\ell = 1, n = 20$ (i.e. we did not try to fit either the inclination angle of the star, or for rotational splitting). Fig. 1 shows the result of the fit, overplotted on the PSD of the light curve optimized for asteroseismology. The frequencies of the 21 fitted modes are given in Table A1.

Model fitting is based on a grid of stellar models evolved from the pre-main sequence to the red-giant branch using the MESA code (Paxton et al. 2011, 2013, 2015), version 10398. The OPAL opacities (Iglesias & Rogers 1996), the GS98 metallicity mixture (Grevesse & Sauval 1998) and the Eigenfrequencies were computed

Figure 1. PSD of the asteroseismic optimized light curved (in light grey) at the natural resolution (no oversampling is performed) with a 11 points boxcar-smoothed version over-plotted in dark grey. The result of the APOLLINAIRE fit is shown in cyan.

in the adiabatic approximation using the ADIPLS code (Christensen-Dalsgaard 2008). The grid is composed of masses from $1.25 M_{\odot}$ to $1.63 M_{\odot}$ with a step of $\Delta M_{\odot} = 0.01 M_{\odot}$, initial abundances $[M/H]$ from -0.10 to 0.40 with a step of 0.05 , mixing length parameters (α) from 1.5 to 2.2 and step of $\Delta\alpha = 0.1$ and overshooting parameter (for the Herwing prescription) f_{ov} from 0 to 0.04 and step of 0.01 . The initial metallicity Z and helium abundance Y were derived from $[M/H]$, constrained by taking a Galactic chemical evolution. Diffusion was not taken into account. As the 1D stellar evolution models do not properly model the outer turbulent layers of stars, we apply surface corrections. More details can be found in Pérez Hernández et al. (2019).

A χ^2 minimization, including p-mode frequencies and spectroscopic data, was applied to the grid of models. The procedure is described in Pérez Hernández et al. (2019). The only difference is that here we have not used the luminosity derived from *Gaia* as an input parameter. To estimate the uncertainty in the output parameters we assumed normally distributed uncertainties for the observed frequencies, and for the spectroscopic parameters. We then search for the model with the minimum χ^2 in every realization, and report mean and 1σ uncertainty values in Table 1. In addition we have done a χ^2 minimization without considering the $\log g$ derived from the spectroscopic data but the results are the same within errors. Fig. 2 shows the échelle diagram obtained by folding the PSD module $\Delta\nu$. The stellar model p-mode frequencies are represented together with the fitted frequencies including the errors.

The results from our spectral analysis, SED fit, and asteroseismic analysis are provided in Table 1, alongside the corresponding values from Paper I. The values from the various methods are in good agreement with each other (most are within 1σ of each other, and all are less than 2σ discrepant), and we adopt the asteroseismic stellar mass and radius values. Many of the stellar parameters computed here differ significantly from the Paper I values. Specifically, the star is significantly smaller, denser, and older than previously thought.

3.4 Stellar distance

The advent of *Gaia* EDR3 (Gaia Collaboration 2016, 2021) and its exquisite parallax measurements allows us to improve upon the stellar characterization of Paper I. K2-99 can be found in the *Gaia* EDR3 catalogue with the identifier 3620612011248988416. A simple inversion of the parallax gives the distance to K2-99 as 518 ± 5 pc. This is smaller than the value determined in Paper I (606 ± 32 pc), but is consistent within 3σ .

⁴<https://gitlab.com/sybreton/apollinaire>

Table 1. Stellar parameters for K2-99. As explained in Section 3.3, we adopt the values of stellar mass and radius resulting from our asteroseismic analysis.

Parameter	unit	Paper I	SME	SED	Asteroseismology
$T_{\star, \text{eff}}$	K	5990 ± 40	6048 ± 70	6051 ± 33	6069 ± 92
$\log g_{\star}$	[cgs]	3.67 ± 0.04	3.77 ± 0.10	3.76 ± 0.05	3.783 ± 0.004
$v \sin i_{\star}$	km s^{-1}	9.3 ± 0.5	9.8 ± 1.0	–	–
[Fe/H]	dex	$+0.2 \pm 0.05$	$+0.2 \pm 0.05$	$+0.2 \pm 0.01$	$+0.2 \pm 0.07$

Figure 2. Échelle diagram, that is frequency as a function of the frequency modulo $\Delta\nu$ and with colours representing the power of the PSD, darker meaning higher power, of K2-99 in the region where the oscillation modes are detected. The cyan squares with symmetric error bars are the frequencies of the modes extracted. The blue circles represent the frequencies of the stellar model after a correction by surface effects as detailed in Pérez Hernández et al. (2019) were applied. From left to right each vertical ridge corresponds to the modes $\ell = 2, 0$, and 1.

4 JOINT MODELLING OF TRANSIT LIGHT CURVE AND RVs

4.1 Method

We combine the newly-obtained RVs with the RVs reported in Paper I (Tables B1 and B2), the C6 long-cadence K2SC (Aigrain, Parviainen & Pope 2016) light curve, and the new short-cadence C17 light curve (Section 2.2) and fit them simultaneously. We perform the fit using the Transit Light Curve Modeller (TLCM), which was previously used in Paper I (as well as in numerous other papers), and is now fully described by Csizmadia (2020). In addition to the transit and RV curve which we fitted for the inner planet in Paper I, we also fit a second Keplerian RV component.

There is some residual correlated noise in the C17 light curve, evidenced by a slight variation in depth between transits, which may be the result of instrumental systematics, and/or stellar activity. We model this using the wavelet approach of Carter & Winn (2009), as implemented in TLCM (Csizmadia 2020; Csizmadia et al. 2021). We are confident that this approach yields the correct transit depth, as our results are consistent with those obtained from fitting the C6 light curve alone, and with fitting the long-cadence C17 light curve produced with the EVEREST pipeline (Luger et al. 2016).

We fit for a total of 22 parameters with TLCM. For K2-99 b, we fit the orbital period (P_b), the epoch of mid-transit ($t_{0,b}$), the scaled semimajor axis (a_b/R_{\star}), the ratio of planetary to stellar radii (R_b/R_{\star}), the transit impact parameter (b_b), two parameters relating to the orbital eccentricity e_b and argument of periastron w_b ($\sqrt{e_b} \sin \omega_b$ and $\sqrt{e_b} \cos \omega_b$), and the RV semi-amplitude (K_b). We also fit for the white noise (σ_w) and red noise (σ_r) levels in the light curve (defined as per Carter & Winn 2009), and the stellar limb-darkening parameters u_+ and u_- (which are related to the quadratic coefficients u_a and u_b by $u_+ = u_a + u_b$ and $u_- = u_a - u_b$). For K2-99 c, we fit P_c , the epoch of periastron ($t_{\text{peri},c}$), $\sqrt{e_c} \sin \omega_c$, $\sqrt{e_c} \cos \omega_c$, and K_c . We also fit for the systemic RV (γ), and four instrumental RV offsets ($\gamma_{2-1}, \gamma_{3-1}, \gamma_{4-1}, \gamma_{5-1}$).

TLCM uses a Markov chain Monte Carlo (MCMC) algorithm to sample the posterior parameter space. A total of 40 MCMC chains, each of 340 000 steps were used, with the first 6000 steps discarded as burn-in. We used widely-spaced uniform priors on the fitted parameters, centred on the results from Paper I. Since the stellar density, $\rho_{\star} = 126 \pm 3.8 \text{ kg m}^{-3}$, is determined from asteroseismology (Section 3.3), we place a Gaussian prior on this quantity in the TLCM fit.

4.2 Results

The resulting best fit (defined as the median of the MCMC posterior distribution) to the transit light curve of K2-99 b is shown in Fig. 3. The RV data are shown as a function of time in Fig. 4, alongside the best-fitting model. Fig. 5 shows the RV data as a function of orbital phase for each planet, with the best-fitting model for the other planet subtracted from both the data and model in each case.

4.2.1 Stellar density

Fitting the data as described in the previous section, but omitting the prior on ρ_{\star} results in a best-fitting stellar density, $\rho_{\star} = 163 \pm 9 \text{ kg m}^{-3}$, which is 3.8σ away from the asteroseismic value. The fitted parameters in the two cases are consistent within 1σ , with the exception of b_b and a_b/R_{\star} , which differ by around 2 and 3σ , respectively.

4.2.2 K2-99 c

We find that the outer planet has an orbital period $P_c = 523.1 \pm 1.4 \text{ d}$, and an RV semi-amplitude, $K_c = 166 \pm 2 \text{ m s}^{-1}$, corresponding to a minimum mass, $M_c \sin i_c$ of $8.2 \pm 0.2 M_{\text{Jup}}$. This minimum mass is

Figure 3. Phase-folded transit light curve. The full light curve from K2 Campaigns 6 and 17 is shown as grey circles, the same data binned in phase to the equivalent of 10 min is shown as blue squares. The wavelet model of the correlated noise is subtracted from the data, and our best-fitting model is indicated with a solid green line.

Figure 4. RV as a function of time. All 93 RV measurements (including those already presented in Paper I) are shown here. Measurements from FIES are represented by purple circles, HARPS by downward-pointing green triangles, HARPS-N by upwards-pointing red triangles, Tull by blue diamonds, and HIRES by orange squares. Our best-fitting model is shown as a solid black line. The residuals to this fit are shown in the lower panel.

compatible with both a high-mass planet (for $i_c \gtrsim 40^\circ$), and a brown dwarf (for smaller values of i_c). Like that of the inner planet, the outer planet's orbit is significantly eccentric, with $e_c = 0.211 \pm 0.009$. The orbital distance of 1.43 ± 0.01 au means that K2-99 c is too hot to be in the habitable zone, even according to the ‘optimistic habitable zone’ of Kopparapu et al. (2013). This remains true, even if one considers the apastron distance of around 1.7 au, instead of the semimajor axis.

Figure 5. RV as a function of orbital phase for K2-99 b (upper panel) and K2-99 c (lower panel). In each panel, our best-fitting model is shown as a solid black line, and the colour and shape coding of the points is identical to Fig. 4. Note that the orbital phase for planet ‘c’ is computed with respect to the predicted time of mid transit for that planet.

4.2.3 K2-99 b

We improve our knowledge of the parameters describing K2-99 b, and present them alongside those derived in Paper I in Table 2. The precision of the orbital period measurement is improved by a factor of around 30, allowing the transit time to be predicted to a precision less than 20 min for over two decades.

Most other parameters are in good agreement with the values from Paper I, but there are some notable exceptions. Our newly-determined value of the scaled orbital semimajor axis for the inner planet, a_b/R_* , is significantly larger than our previous measurement. The new value of ω_b also differs by more than 2σ from the Paper I value. We re-examined our Paper I analysis, and conclude that these parameters were affected by a problem with our analysis in Paper I. We found that in our earlier analysis, the $e_b \sin \omega_b$ parameter⁵ did not converge properly. The current version of TLCM uses the Gelman–Rubin statistic and estimated sample size to ensure that all parameters are well sampled, but these tests were not used in Paper I. This problem with $e_b \sin \omega_b$ resulted in a biased determination of ω_b . The eccentricity was not badly affected, since $e_b \cos \omega_b$ was determined correctly, and $e_b \cos \omega_b \gg e_b \sin \omega_b$ in this case. However, in order to compensate for this incorrect $e_b \sin \omega_b$, the values of a_b/R_* and b_b were also biased.

We also performed fits to just the C6 light curve, and just the C17 light curve and found in each case values of a_b/R_* consistent with our new value in Table 2. As an additional check, we also fitted the RVs with RVLIN (Wright & Howard 2009), and recovered values of e_b , ω_b , K_b , P_c , $t_{\text{peri}, c}$, e_c , ω_c , and K_c in good agreement with our values from TLCM.

⁵The version of TLCM used in Paper I fitted the orbital eccentricity, e_b and argument of periastron, ω_b through $e_b \sin \omega_b$ and $e_b \cos \omega_b$. However, in order not to inadvertently impose a non-uniform prior on e (e.g. Ford 2006; Anderson et al. 2011; Eastman, Gaudi & Agol 2013), the current version of TLCM fits instead for $\sqrt{e_b} \sin \omega_b$ and $\sqrt{e_b} \cos \omega_b$.

Table 2. System parameters from TLMC modelling.

Parameter	Symbol	Unit	Smith et al. (2017)	This work
K2-99 b:				
Orbital period	P_b	d	18.249 ± 0.001	18.24783 ± 0.00003

[†] Assuming a planetary albedo of zero, and isotropic heat redistribution. [‡] If the outer planet does indeed transit.

Additionally, some uncertainties were underestimated in Paper I. Error estimation in the current version of TLMC is performed by applying the ‘16–84 percent’ rule to the MCMC posterior distribution (as recommended by e.g. Hogg & Foreman-Mackey 2018). Previously, the ‘varying χ^2 ’ method was used, which can lead to underestimated error bars, because it assumes that the uncertainties are Gaussian, and that the model is linear (Andrae 2010).

We also find a significantly smaller planet radius than previously; this is driven by the smaller stellar radius resulting from our new analysis (Section 3). The new planetary radius of $1.06 \pm 0.01 R_{\text{Jup}}$ indicates an uninflated planet, as expected from empirical studies of gas giants. Sestovic, Demory & Queloz (2018), for instance, found no evidence for an inflated population of planets in the mass range $0.37\text{--}0.98 M_{\text{Jup}}$ above an insolation of $1.6 \times 10^6 \text{ W m}^{-2}$. K2-99 b receives less than half of this insolation, even when at periastron.

Finally, the stellar limb-darkening parameters, u_+ and u_- , also vary from those reported in Paper I. We tried fixing u_+ and u_- to the values obtained in Paper I, and note no resulting difference to less than 1σ in any other parameters.

5 SEARCH FOR ADDITIONAL SIGNALS IN THE DATA

5.1 Transit timing variations

5.1.1 Predicted transit timing variation

The presence of additional planets in a system containing a transiting planet is known to induce variations in the timings of the transits. Analysing these transit timing variations (TTVs) can lead to important insights into system architecture, such as inferring the presence

Figure 6. Predicted TTVs for K2-99 b, for a range of values of the orbital inclination of K2-99 c (coloured lines). The line thickness represents the uncertainties in the expected TTVs based on uncertainties in the planet masses and orbit parameters taken from Table 2. Our measured mid-transit times (Table 3) are shown as black crosses, and the time of future TESS observations of K2-99 (Sectors 46 and 50) are indicated with vertical shaded regions (see Section 6.2.2).

Table 3. Fitted times of mid-transit for individual transits of K2-99 b, their uncertainties (in days and in minutes), and the deviations (O-C) from the ephemerides presented in Paper I and in Table 2.

<i>E</i>	$T_c - 2450000$ BJD _{TDB}	σ_{T_c} d	σ_{T_c} min	(O-C) / min	
				Paper I	Table 2
0	7233.8264	0.0033	4.8	4.9	-1.5
1	7252.0730	0.0024	3.5	1.5	-3.3
2	7270.3218	0.0029	4.2	1.2	-1.8
3	7288.5698	0.0039	5.6	-0.3	-1.5
52	8182.7125	0.0016	2.3	-84.2	0.7
53	8200.9607	0.0016	2.3	-85.4	1.3
54	8219.2094	0.002	2.9	-85.9	2.5
55	8237.4565	0.0011	1.6	-88.5	1.6

of additional planets, and measuring planet masses (see e.g. Agol & Fabrycky 2018 for a review). In order to compute the theoretically expected TTVs induced by the presence of K2-99 c, we carried out n-body simulations using REBOUND (Rein & Liu 2012), using the values reported in Table 2 for the planet and orbit parameters. Our simulations predict a TTV amplitude of around two to three minutes for most possible values of i_c (Fig. 6). The predicted TTVs are substantially larger for nearly face-on orbits ($i_c = 10^\circ$ is the smallest value included in Fig. 6), but TTVs of even this magnitude cannot be ruled out using our measured transit times, because the uncertainties are too large (Table 3).

5.1.2 Measured transit times

We fitted for the times of each of the eight observed transits of planet ‘b’. This was done by fixing all parameters, except the transit epoch, to the best-fitting values listed in Table 2. TLMC was then used to fit only a single transit taken from the K2SC long-cadence light curve (C6) or the short-cadence light curve described in Section 2.2 (C17). The resulting transit times and 1σ uncertainties are listed in Table 3. We note that the uncertainties on the C6 transit times are somewhat larger than those reported in Paper I, and attribute this difference to the change of error estimation method within TLMC (See Section 4.2.3).

We first compared the observed transit times to those predicted using the orbital ephemeris from Paper I, finding that all the C17 transits occur between 84 and 89 min earlier than predicted. However, the 1σ uncertainties on the times predicted by that ephemeris are around 80 min. Using the ephemeris reported in Table 2, we find a maximum difference between predicted and observed transit times of 2.5 min. Given that the magnitude of the O-C differences are very similar to the timing precision of each transit, we conclude that there is no evidence for any deviation from a linear transit ephemeris. We also note that given the expected TTV amplitude (Section 5.1.1) has a magnitude similar to the precision of our measurements, we do not expect to be able to measure the TTV signal.

5.2 Occultation

We find no evidence for the occultation of planet ‘b’ in the light curve of K2-99. By fitting for an occultation at the orbital phase expected from the e_b and ω_b in Table 2 using TLMC, we place a 3σ upper limit on the occultation depth of 130 ppm. That the occultation is not detected is unsurprising, given the large luminosity ($8 \pm 0.5 L_\odot$) of the host star, and the moderate planetary equilibrium temperature.

5.3 Additional periodicity in the RVs

After subtracting the best-fitting Keplerian models for both planets, and the fitted instrumental offsets from our RVs, we searched the residuals for the presence of additional periodic signals, using the ASTROPY (Astropy Collaboration 2013; Price-Whelan et al. 2018) implementation of the Lomb–Scargle periodogram. We found no further periodic signals with a false-alarm probability less than 10 per cent, and conclude that the RVs offer no evidence for the presence of a third planet, or for stellar rotation.

We also tried fitting for a radial acceleration term in our joint modelling with TLMC, which returned $\dot{\gamma} = 0.0144 \pm 0.0046 \text{ m s}^{-1} \text{ d}^{-1}$. The Bayesian Information Criterion of the model with non-zero $\dot{\gamma}$ is lower by 7.8 which, along with the 3σ detection of $\dot{\gamma}$, could be interpreted as evidence in favour of the presence of an RV trend. However, we see no evidence of a power excess at low frequencies in the Fourier transform of the RV residuals. Such an excess is expected in the presence of a genuine radial acceleration, and a simple simulation using our RV timestamps and uncertainties confirms this. We further note that there may be a degeneracy between the radial acceleration term and the offsets between instruments (Knutson et al. 2014). The apparent presence of the trend is also strongly reliant on the most-recent HARPS observation. We conclude that the evidence for the presence of an RV trend is not compelling, and therefore choose to adopt the model with no radial acceleration term. We note that the two models are very similar to each other; no parameters vary between the models by more than 1σ .

If the apparent acceleration term were real, it could indicate the presence of a third planet in orbit around K2-99. Following the same approach as we did for the much larger acceleration detected in Paper I, we find that $M_d/a_d^2 > 0.08 M_{\text{Jup}} \text{ au}^{-2}$. If we assume that the orbit of the putative planet ‘d’ is not highly eccentric, then the orbital period, P_d must be at least twice the baseline of our RV observations, $P_d > 2294 \text{ d}$ which leads to a limit on the size of the orbit, $a_d > 3.85 \text{ au}$. A $2 M_{\text{Jup}}$ planet orbiting at 5 au or a brown dwarf at several tens of au could induce an acceleration of this magnitude. Finally, we note that further RV observations during K2-99’s next observing season will enable the model with a radial acceleration to be ruled out with greater certainty.

Figure 7. Probability that K2-99 c transits, as a function of the maximum mutual inclination angle between the orbital planes of planets ‘b’ and ‘c’, $\lambda_{bc, \max}$ (solid blue line). The *a priori* transit probability of 0.92 per cent is shown as a dashed red line.

5.4 Frequency analysis of the activity indicators

We further assessed the planetary nature of the Doppler signal at 523 d by performing a frequency analysis of the bisector inverse slope (BIS) and FWHM of the CCF, as well as of Mount Wilson S -index (S_{MW}). We used the generalized Lomb–Scargle periodogram (Zechmeister & Kürster 2009). We found no significant signal with a false-alarm probability⁶ (FAP) lower than ~ 8 per cent. This acts as a sanity check that the RV signal with a period of 523 d is due to the Doppler reflex motion induced by an additional planet orbiting K2-99. We also used SERVAL (Zechmeister et al. 2018) to measure additional activity indicators, namely, the chromatic index, differential line width, and $H\alpha$, sodium NaD1 and NaD2 indexes. We found no significant periodic signal (FAP < 0.1 per cent) in any of these indicators either, further corroborating our results.

6 POSSIBLE TRANSITS OF K2-99 C

6.1 The probability of transits

Ignoring the presence of the inner planet, we can calculate the *a priori* probability that the system is aligned such that the outer planet transits. This probability, calculated using equation (9) of Winn (2011), but neglecting the planetary radius, such that a transit is defined as events where the star is occulted by at least half of the planetary disc, is 0.9 per cent. However, given the apparent propensity for at least some multiplanetary systems to have low mutual inclination angles (e.g. Fabrycky et al. 2014), we might reasonably expect this probability to be higher.

The range of orbital inclination angles, i_c , for the outer planet that result in transits is $i_c \geq 89.478 \pm 0.007$ degrees. Following an approach similar to that of Beatty & Seager (2010) for HAT-P-13 b and Espinoza (2019) for GJ 357 d, we calculate the probability that K2-99 c transits for a range of mutual inclination angles (Fig. 7). We randomly draw values of the following parameters from normal distributions centred on the values listed in Tables 1 and 2, and with standard deviations equal to the error bars listed in the same table: R_* ,

⁶We estimated the false-alarm probability using the bootstrap method described in Murdoch, Hearnshaw & Clark (1993).

Table 4. Predicted times of mid-transit for K2-99 c, if it is transiting, from the ephemeris presented in Table 2.

E	$T_c - 2\,400\,000$ BJD _{TDB}	σ_{T_c} d	Date
3	59670.7	4.6	2022 April 1
4	60192.9	5.9	2023 September 5
5	60715.1	7.3	2025 February 8
6	61237.3	8.7	2026 July 15

M_* , i_b , P_c , e_c , ω_c . We then compute i_c by taking the drawn value of i_b and adding the mutual inclination angle, λ_{bc} , which is drawn from a distribution which is uniform between $-\lambda_{bc, \max}$ and $\lambda_{bc, \max}$. This process is repeated a number of times for a single value of $\lambda_{bc, \max}$ to calculate a transit probability, before $\lambda_{bc, \max}$ is incremented and the whole process repeated.

As expected, the transit probability is significantly enhanced above the *a priori* probability for small mutual inclinations, with a transit probability of just over 10 per cent for mutual inclinations less than 5° , rising to more than 20 per cent for $\lambda_{bc, \max} = 2^\circ$.

One of the results from the original *Kepler* mission (Koch et al. 2010) is that tightly-packed multiplanet systems exhibit a flat geometry, with Fabrycky et al. (2014) finding typical mutual inclination angles between orbital planes of just one or two degrees. However, the K2-99 system is not representative of the tightly-packed systems of relatively small planets that dominate the *Kepler* sample. Indeed, the so-called ‘*Kepler* dichotomy’, first observed by Lissauer et al. (2011), suggests that there is an excess of systems where only a single planet is observed to transit.

The *Kepler* dichotomy has been interpreted as evidence for two populations of systems: flat multiplanet systems with low mutual inclinations, and a second population consisting of either lone planets, or multiplanet systems with high mutual inclinations. Albrecht et al. (2013) and Morton & Winn (2014) found that the stellar obliquities of single transiting planet systems are systematically larger than for systems with multiple transiting planets, suggesting that single transitors represent a dynamically hotter population. The obliquity of K2-99 b is unknown, but if K2-99 belongs to this latter population, like Kepler-108 which has two giant planets on 49-d and 190-d orbits and a mutual inclination angle of $24^{+11}_-8^\circ$ (Mills & Fabrycky 2017), then it is probably rather unlikely that K2-99 c transits.

More recently Zhu et al. (2018) and Millholland et al. (2021) have proposed models that explain the apparent *Kepler* dichotomy with a continuous distribution of relatively small mutual inclinations. Here, the mutual inclination depends strongly on the intrinsic multiplicity of the system, such that systems that contain more planets are geometrically flatter, and there is no true dichotomy.

6.2 The observability of transits

Motivated by the previous section, in which we determine that there is a small, but significant chance that K2-99 c transits, we calculate the epoch of mid-transit for ‘c’, assuming that its orbital inclination, i_c , is equal to 90° . This epoch of mid-transit (see Table 2), along the P_c , allows us to calculate a list of potential future transits of the outer planet (Table 4). The RA of K2-99 results in an observing season that is centred on April, so the target will be very well observable during the next potential transit (in 2022 April).

Unfortunately, the uncertainty on this mid-transit time is relatively large, and so a photometric monitoring campaign of several weeks’

duration would be required to cover the transit window. Given the mass of K2-99 c (Table 2), we expect its radius and hence transit depth to be similar to those of the inner planet (around 0.2 per cent). The duration of a central ($i_c = 90^\circ$, $b = 0$) transit is calculated to be 32.1 ± 0.5 h, with ingress and egress durations of around 1.3 h, but these durations would be somewhat shorter for a transit with a moderate impact factor.

6.2.1 Prospects for observing the transit of K2-99 c from the ground

The combination of depth and duration make this an extremely challenging transit to detect from the ground. Nevertheless, the ground-based Next Generation Transit Survey (NGTS; Wheatley et al. 2018) has recently demonstrated its ability to detect extremely shallow (<0.1 per cent) transits using several telescopes in combination (Smith et al. 2020). NGTS has also proven its ability to recover the transits of long-period objects by monitoring lengthy transit windows (Gill et al. 2020a,b; Bryant et al. 2021). It may therefore be possible to detect a transit of K2-99 c with NGTS, although it would require committing several telescopes to observe for a period of some weeks.

6.2.2 Prospects for observing the transit of K2-99 c from space

The large transit window necessitates an infeasibly large time commitment for a targeted space-borne telescope, such as the CHaracterising ExOPlanet Satellite (CHEOPS; Benz et al. 2021). The Transiting Exoplanet Survey Satellite (TESS; Ricker et al. 2015) has not observed K2-99 to date; however, observations are expected⁷ during TESS' fourth year of operations (Sectors 46 and 50). No transit of K2-99 c is expected during S46 (2021 December), but the S50 observations are serendipitously timed to cover almost all of the 2022 April transit window. Current plans are for this sector to be observed from 2022 March 26 to 2022 April 22, meaning that all of the 9-d long 1σ transit window, and much of the 18-d long 2σ transit window will be observed. These planned TESS observations surely represent the best possibility of detecting the transit of K2-99 c.

Each TESS sector consists of two orbits of the satellite, between which there is a gap at perigee when the spacecraft is oriented for data downlink, and no observations are made. These gaps have a duration between 22 and 40 h (based on Sectors 1–35). This pause in TESS observations around 2022 April 8/9, as well as a few days before the start of TESS observations would ideally be filled by CHEOPS observations, or by ground-based photometric observations from multiple longitudes, so that the transit is not missed should it occur during this time.

6.3 The value of transits

Detecting the transit of K2-99 c would be a valuable discovery, allowing measurement of its radius. Cold Jupiters are not subject to extreme insolation and tidal heating, allowing planetary evolution and interior models to be tested when planetary masses and radii are known. Relatively few such objects have been discovered so far; only 13 transiting planets with an orbital period longer than 500 d are currently listed in the NASA Exoplanet Archive.⁸ Of these 13, only eight have well-determined orbital periods, with the remainder having period uncertainties of greater than 20 per cent, or

⁷According to the Web TESS Viewing Tool; <https://heasarc.gsfc.nasa.gov/cgi-bin/teess/webteess/wtv.py>

⁸<https://exoplanetarchive.ipac.caltech.edu/>, accessed 2021 May 07.

upper limits only. The eight transiting planets with well-determined periods greater than 500 d are all *Kepler* targets, with no RV measurements of the planetary mass. Indeed, only one transiting planet, the circumbinary Kepler-47c (Orosz et al. 2012), is known with an orbital period greater than 300 d, and a well-determined mass, radius, and period. If a transit of K2-99 c is detected, it would be only the sixth exoplanet more massive than Saturn with measured mass, radius, and orbital period greater than 100 d, making it an extremely valuable object for further study.

7 SYSTEM ARCHITECTURE

7.1 Orbital inclination of K2-99 c

As we discussed in Section 6, the inclination angle of the outer planet's orbit, i_c , is unknown. We note that if the orbital inclination of the outer planet is less than about 40° , its mass would be above the deuterium burning limit of approximately $13 M_{\text{Jup}}$, placing it in the brown-dwarf mass regime. The evolutionary models of Petrovich & Tremaine (2016) suggest that if K2-99 b is undergoing high-eccentricity migration, then K2-99 c is likely to have a large mutual inclination.

Astrometry in combination with RVs has the potential to fully solve the orbit of an exoplanet, determining the inclination angle, and hence the true planetary mass (e.g. Benedict et al. 2002). The final data release from *Gaia* is expected to enable this for a significant number of systems, as well as allowing the discovery of new exoplanets (Perryman et al. 2014). Even before this data release, for some systems the excess astrometric noise parameter, ϵ , can enable constraints to be placed on the inclination angle (Kiefer 2019; Kiefer et al. 2019, 2021). Unfortunately given the distance of K2-99, the size of the astrometric orbit of K2-99 c is too small to allow a meaningful constraint on i_c , despite the small value of $\epsilon = 0.29$ mas in *Gaia* DR1 (Kiefer, private communication).

7.2 A dynamically 'hot' system?

As we pointed out in Paper I, a measurement of the obliquity of K2-99 b (λ_b) would be very interesting. This remains the case, and would also offer insight into whether or not the system is dynamically 'hot', as discussed in Section 6. Asteroseismology can offer a means to determine the inclination of the stellar rotation axis, and hence the obliquity of a planet for which the inclination angle is known. This technique (Chaplin et al. 2013) relies on a light curve with a signal-to-noise greater than that of our C17 light curve, and so we are not able to detect an asteroseismic rotation signature. The best prospect for measuring λ_b is therefore probably via the Rossiter–McLaughlin effect.

7.3 Alignment of eccentricities

Both planets in the K2-99 system have similar orbital eccentricities ($e_b = 0.22 \pm 0.02$ and $e_c = 0.211 \pm 0.009$), although the apses of the two orbits are not aligned, $|\Delta\omega_{\text{sky}}| = |\omega_b - \omega_c| = 40^\circ \pm 4.5^\circ$. Dawson & Chiang (2014) studied warm Jupiters on eccentric orbits with giant companions also on an eccentric orbit. They found that in such systems, the orbits of the two planets tend to be apsidally misaligned, with an apparent clustering around $|\Delta\omega_{\text{sky}}| = 90^\circ$. Motivated by the apparent discrepancy of K2-99 with this observation, we generated an updated version of fig. 1A of Dawson & Chiang (2014) (Fig. 8). We used the same definitions and thresholds as Dawson & Chiang (2014), namely plotting pairs of planets where each planet has a 2σ detection of eccentricity, and $\sigma_\omega < 40^\circ$. Using the NASA Exoplanet

Figure 8. Sky-projected apsidal alignment as a function of orbital angular momentum ratio for a total of 67 pairs of planets in 45 systems, after Dawson & Chiang (2014). The red circles represent warm Jupiters with a single outer companion orbiting beyond 1 AU. K2-99 is shown by a blue square. The distribution of apsidal alignments for all points is shown as a grey histogram on the right hand side of the plot. Data is from the NASA Exoplanet Archive (see Section 7.3 for full details).

Archive, we calculated $|\Delta\omega_{\text{sky}}|$ and the orbital angular momentum ratio (orbital angular momentum = $M_p \sin i_p \sqrt{a_p(1 - e_p^2)}$).

Our sample is significantly larger than that available to Dawson & Chiang (2014); in Fig. 8 we plot 67 pairs of planets, including 17 warm Jupiters with a single outer companion, compared to 40 pairs and eight warm Jupiters in Dawson & Chiang (2014). With this larger sample, we find no evidence for a clustering of apsidal alignment around 90° for the warm Jupiter systems. Fig. 8 does however indicate that an alignment of orbital apses, such that $|\Delta\omega_{\text{sky}}| \approx 0^\circ$ and $|\Delta\omega_{\text{sky}}| \approx 180^\circ$ may be favoured for systems in general. Fig. 8 also reveals that there are more systems with $|\Delta\omega_{\text{sky}}| < 90^\circ$ than with $|\Delta\omega_{\text{sky}}| > 90^\circ$. A two-sided binomial test (neglecting uncertainties in $|\Delta\omega_{\text{sky}}|$) gives $p = 0.036$, indicating that this imbalance is significant at the 5 per cent level. However, when points whose 1σ error bars straddle the 90° -line are neglected, we find $p = 0.23$ which offers no evidence in favour of an imbalance in the distribution of $|\Delta\omega_{\text{sky}}|$.

8 CONCLUSIONS

We have used newly-obtained RVs to measure the mass, and determine the orbit of K2-99 c. We refined our knowledge of K2-99 the star via Gaia parallax measurements, and an asteroseismic analysis of short-cadence photometry from K2’s Campaign 17. We also improved our knowledge of the inner planet, K2-99 b, finding it to be non-inflated. Upcoming TESS observations of K2-99 in 2022 April offer the tantalizing possibility of detecting the transit of K2-99 c, if

the orbital planes of the two planets have a small mutual inclination angle. Alternatively, if the mutual inclination angle is large, K2-99 c may have played an important role in the inward migration of K2-99 b, making the K2-99 system an important laboratory for our understanding of planetary migration. The full 3D geometry of the system may be revealed in the future through a measurement of the spin-orbit alignment of K2-99 b and a measurement of the inclination of K2-99 c via detection of its transit, or from astrometry.

ACKNOWLEDGEMENTS

This work is done under the framework of the KESPRINT collaboration (<http://www.kesprint.science>). KESPRINT is an international consortium devoted to the characterization and research of exoplanets discovered with space-based missions.

Based on observations made with ESO Telescopes at the La Silla Observatory (Chile) under programmes 097.C-0948(A), 099.C-0491(B), 099.C-0491(A), 0100.C-0808(A), 0101.C-0829(A), 60.A-9700(G), and 1102.C-0923(A), and the TNG telescope at Roque de Los Muchachos Observatory (Spain) under programmes A33TAC_15, A34TAC_10, OPT17A_64, A35TAC_26, OPT17B_59, CAT17B_99, CAT18A_130, OPT18A_44, A37TAC_37, OPT18B_52, and A38TAC_26.

This paper includes data collected by the *Kepler* mission. Funding for the *Kepler* mission is provided by the NASA Science Mission directorate. Some of the data presented in this paper were obtained from the Mikulski Archive for Space Telescopes (MAST). STScI is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. Support for MAST for non-*HST* data is provided by the NASA Office of Space Science via grant NNX09AF08G and by other grants and contracts.

This research has made use of the Exoplanet Follow-up Observation Program website, and the NASA Exoplanet Archive, which are operated by the California Institute of Technology, under contract with the National Aeronautics and Space Administration under the Exoplanet Exploration Program.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2013-2016) under grant agreement No. 312430 (OPTICON).

This research has made use of NASA’s Astrophysics Data System, the SIMBAD data base, operated at CDS, Strasbourg, France, and the Exoplanets Encyclopaedia at exoplanet.eu. We also used ASTROPY, a community-developed core PYTHON package for Astronomy (Astropy Collaboration 2013; Price-Whelan et al. 2018).

This work has made use of data from the European Space Agency (ESA) mission *Gaia* (<https://www.cosmos.esa.int/gaia>), processed by the *Gaia* Data Processing and Analysis Consortium (DPAC, <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the *Gaia* Multilateral Agreement.

KWFL, SC, and APH were supported by Deutsche Forschungsgemeinschaft grants HA3279/12-1 and RA714/14-1 within the DFG Schwerpunkt SPP 1992, Exploring the Diversity of Extrasolar Planets. SC is also supported by Deutsche Forschungsgemeinschaft Research Unit 2440: ‘Matter Under Planetary Interior Conditions: High Pressure Planetary and Plasma Physics’. HJD acknowledges support from the Spanish Research Agency of the Ministry of Science and Innovation (AEI-MICINN) under grant PID2019-107061GB-C66, DOI: 10.13039/501100011033. JK gratefully acknowledge the support of the Swedish National Space Agency (SNSA; DNR 2020-00104). SM acknowledges support by the Spanish Ministry of Science and Innovation with the Ramon y Cajal fellowship number

RYC-2015-17697 and the grant number PID2019-107187GB-I00. SNB and RAG acknowledge the support of the PLATO CNES grant. LMS and DG gratefully acknowledge financial support from the CRT foundation under Grant No. 2018.2323 ‘Gaseous or rocky? Unveiling the nature of small worlds’. We thank Erik Petigura for his contribution to the collection and analysis of the Keck/HIRES data. Finally, we thank the referee for their careful reading of the manuscript and constructive suggestions, which resulted in improvements to this paper.

DATA AVAILABILITY

The data underlying this article are available in the article and at the following public archives. The HARPS spectra can be found at the ESO archive;⁹ the HARPS-N spectra at the TNG archive;¹⁰ the HIRES spectra at EXOFOP-K2;¹¹ and the K2 data at MAST.¹²

BIS is the bisector span, FWHM is the full width at half-maximum of the cross-correlation function, S_{MW} is the Mount Wilson S -index, S/N is the signal-to-noise, and T_{exp} is the exposure time. Measurements marked with † were previously presented in [Paper I](#).

Table B2. RV measurements of K2-99, from the FIES, Tull, and HIRES instruments. S_{MW} is the Mount Wilson S -index, and T_{exp} is the exposure time.
