Supporting Information

ABSTRACT: Cationic surfactants are widely used in the colloidal synthesis of noble metal nanoparticles in general, and of Pd nanoparticles in particular, to stabilize them toward aggregate formation in solution and to promote shape-specific particle growth. Despite the benefits at the synthesis stage, these surfactants can be problematic once the nanoparticles are to be applied as they may both geometrically block and electronically alter surface sites that are important for surface chemical reactions. This is particularly relevant in applications like bio- and chemosensors where analyte-nanoparticle surface interactions constitute the actual sensing event. Here, H_2 sensors based on Pd and its alloys are no exception since the dissociation of H_2 on the particle surface is the first step toward hydride formation and thus hydrogen detection, and it has been demonstrated that the presence of surfactant molecules detrimentally affects the hydrogen sorption rate. Here, we therefore develop a scheme to remove cationic surfactants from Pd nanoparticle surfaces by means of subsequent O_2 and H_2 plasma treatment, whose effectiveness we verify by X-ray photoelectron spectroscopy. Furthermore, we find that the plasma treatment both alters the surface structure of the Pd nanoparticles at the atomic level and leads to surface contamination by so-called H_2 plasma swift chemical sputtering of Al, Si and F species present in the plasma chamber, which in combination significantly reduce hydrogen sorption rates and increase apparent activation energies, as revealed by plasmonic hydrogen sorption kinetic measurements. Finally, we show that both these effects can be reversed by mild thermal annealing and that after the complete plasma cleaning–thermal annealing sequence hydrogen sorption rates essentially identical to the ones of neat Pd particles never exposed to cationic surfactants can be achieved. This advertises tailored plasma cleaning and mild heat treatments as an effective recipe for the removal of surfactant molecules from nanoparticle surfaces.

INTRODUCTION

Pd films and nanoparticles, and their derivatives in terms of alloys, find wide application in processes and technologies where the interaction of molecules with their surfaces is a key step, such as in heterogeneous catalysis,^{1–3} gas storage,^{4,5} gas separation membranes,^{6,7} and gas sensors.^{8–12} In this context, the interaction of Pd surfaces with hydrogen gas is an interesting subcategory,^{7,8,13,14} where many applications exploit the exceptional ability of Pd to efficiently dissociate molecular hydrogen (H_2) at ambient conditions and absorb H into its lattice in interstitial sites, eventually forming a hydride.¹⁵ In many of these applications, the kinetics of H_2 dissociation and/or absorption and desorption into/from the interstitial sites in the Pd lattice is a crucial aspect of the targeted performance because it determines, for instance, kinetics of a catalytic reaction,^{16,17} response times of hydrogen sensors,^{9,18–20} or the loading time of a hydrogen storage medium.²¹ It is therefore clear that the state of the surface plays a critical role when defining the barriers of the rate

limiting step, which on a clean Pd surface for hydrogen absorption is the step from the surface to the first subsurface site²² and associative desorption of H_2 from the surface for the reverse process.²³ However, it has also been shown that surface contaminants such as carbon monoxide (CO)^{24–26} and sulfuric or sulfidic compounds (e.g., SO_2 and H_2S),^{27–29} as well as surfactant molecules used for colloidal synthesis of Pd nanocrystals^{30,31} distinctly affect the rate of hydrogen sorption and the corresponding energetics.^{32,33} At the same time, surface contamination is unavoidable upon exposure to ambient conditions or in colloidal Pd nanoparticle synthesis due to the multiple key roles of surfactants/capping agents,

The spectral position of the LSPR peak ($\Delta\lambda_{\text{peak}}$) scales linearly with the H/Pd ratio.⁴⁹

such as solubilizing the initial reagents, directing shape-selected particle growth, and preventing nanoparticle aggregation in suspension.³⁴

Among these capping agents, surfactants of the cationic-type that are based on quaternary ammonium salts, for example, CTAB (cetyltrimethylammonium bromide), CTAC (cetyltrimethylammonium chloride), and TOAB (tetraoctylammonium bromide), are widely used since they adsorb on the nanoparticle surface providing both steric and electrostatic stabilization against aggregation.^{35–38} At the same time, their selective adsorption onto specific crystalline facets constitutes the basis for the shape-controlled synthesis of most metal nanoparticles in general and Pd in particular.^{39–41} However, in this adsorption process, the halide ions (Br^- or Cl^-) bind strongly to the Pd surface^{39,42} and thereby effectively block a significant fraction of surface sites, such as the H_2 dissociation (recombination) sites of particular interest here, from access for other species, which leads to a significant decrease in hydrogen sorption rate.³² Furthermore, the metal-halide bond locally alters the electronic landscape of the surface and thereby the relevant activation barriers during the hydrogen sorption process.³²

To this end, numerous attempts have been made to remove cationic-type surfactant molecules from metallic nanoparticle surfaces using electrochemistry,^{43,44} chemical⁴⁵ or heat-treatment,⁴⁵ and UV-ozone cleaning.^{3,46} While electrochemical cleaning has been shown to be efficient, its applicability is limited. Heat treatment potentially deforms and aggregates the

nanoparticles. In the UV-ozone cleaning process, ionized species of oxygen in combination with UV-light are used to remove the contaminants via chemical reactions between ions and contamination that form readily desorbing volatile compounds.⁴⁷ Despite its effectiveness, UV-ozone cleaning (as well as heat-treatment and chemical cleaning) usually requires long processing times. For example, UV-ozone and heat treatments that remove cationic-type surfactants from Pd surfaces have been reported to take several hours^{33,45} and even more time-consuming chemical cleaning procedures using, e.g., *tert*-butylamine (TBA) solution to remove Br^- take up to 3 days.⁴⁶ In addition, heat and UV-ozone treatments tend to oxidize Pd. Due to those limitations, a more efficient and benign approach to remove cationic-type surfactant molecules from metal nanoparticle surfaces in general and from Pd surfaces in particular is important to be developed.

In this work, we therefore develop and investigate in detail the removal of the three cationic surfactants CTAB, CTAC and TOAB from nanofabricated Pd nanoparticle surfaces by means of H_2 plasma and O_2 plasma, and its impact on the hydrogen sorption properties of these particles, as well as on their surface structure. For this purpose, we use high-resolution X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM) in combination with localized surface plasmon resonance (LSPR) based hydrogen sorption rate measurements.⁹ Specifically, we execute our experiments on the basis of initially surfactant-free nanoparticles immobi-

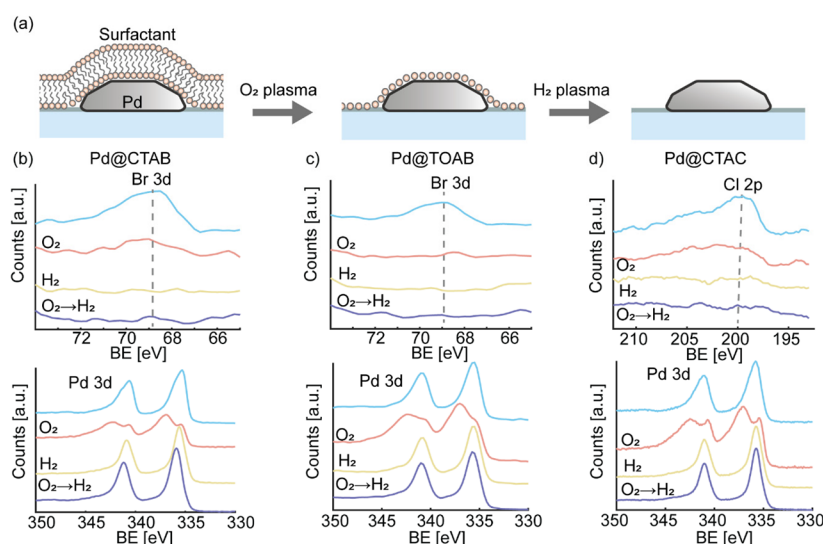

Figure 2. (a) Schematic of surfactant removal using sequential O₂ plasma and H₂ plasma treatment. O₂ plasma removes the surfactants' alkyl tail and likely the non-Pd-binding cations, while H₂ plasma removes the halide cations from the Pd surface. lized on a surface by nanofabrication (rather than actually using colloidal Pd nanoparticles synthesized in solution) that we subsequently expose to different capping agents, following a scheme we have introduced earlier.⁴⁸ This approach enables the tracking of the impact of the cleaning process on the nanoparticle structure and function in an efficient way, since a control experiment from the pristine, surfactant-free, and uncleaned sample is always readily available as the first step of a series of experiments.

RESULTS AND DISCUSSION

The quasi-random arrays of Pd nanoparticles (Figure 1a) used for this study were nanofabricated onto flat fused silica (for optical hydrogen sorption measurements) or oxidized Si wafer (for XPS) substrates using the hole-mask colloidal lithography method described in detail in our previous work^{20,24,48} and in brief in the Methods section. After fabrication, we annealed the nanoparticle arrays at 500 °C for 24 h in 4% H₂ in Ar carrier gas to induce recrystallization into polycrystalline structures with few grains and low index surface facets^{50,51} (Figure 1b). To subsequently self-assemble a bilayer of surfactants onto the particles,^{32,38} we drop-cast CTAB, TOAB, or CTAC water solutions (10 mM), respectively, onto the sample and left it incubate for 24 h (Figure 1c). Excess solution was subsequently rinsed-off with Milli-Q water, followed by drying in a N₂ stream. Here, we note that CTAB and CTAC have similar molecular structures with one long alkyl tail but are distinct in their counterion, i.e., Br[−] in CTAB and Cl[−] in CTAC, with which they bind to the Pd surface^{35,36,39,52} (Figure 1d). At the same time, CTAB and TOAB feature cationic quaternary ammonium but the former has one long alkyl chain, whereas the latter has four shorter tails. As a consequence of the different steric hindrance exhibited by these tails, CTAB and CTAC form a denser layer compared to TOAB, as illustrated schematically in Figure 1d.^{53–55} Finally, to investigate both the impact of the presence of the surfactants and subsequently of the plasma cleaning procedures on the state of surface activity of the Pd nanoparticles, we monitored the hydrogen sorption rate using localized surface

plasmon resonance (LSPR) based sensing, according to the principle illustrated in Figure 1e, which tracks the LSPR peak position while the nanoparticle (de)absorbs hydrogen.⁹ Since the LSPR peak position shift ($\Delta\lambda_{\text{peak}}$) scales linearly with the H/Pd ratio,⁴⁹ its temporal evolution represents the hydrogen sorption rate, which is dictated by the rate-limiting H-diffusion step from the surface to the first subsurface layer for absorption.^{22,56} Hence, it is expected to be directly affected by the presence of surface contamination^{20,25,32,57} and changing surface structure,^{23,58,59} and thus to be well-suited to serve as a model reaction for investigating the impact of plasma cleaning on the surface reactivity of Pd nanoparticles.

To start this investigation, we prepared five samples, wherein one was kept as-is after nanofabrication and annealing to serve as negative control (neat Pd). The remaining three samples were coated with a bilayer of CTAB (Pd@CTAB), CTAC (Pd@CTAC), or TOAB (Pd@TOAB), respectively, using the procedure outlined above. For each surfactant type, the four samples subsequently underwent different treatment: (i) the first sample was kept as-coated, while the remaining three were treated with (ii) O₂ plasma, (iii) H₂ plasma, or (iv) O₂ plasma and H₂ plasma in sequence (see the schematic in Figure 2a and the Methods section for plasma dosage details).

Focusing first on Pd@CTAB, XPS analysis reveals a distinct Br 3d peak (BE \approx 68.8 eV) for as-deposited Pd@CTAB, which decreases significantly after both O₂ and H₂ plasma treatments (Figure 2b). Closer inspection shows that H₂ plasma appears to have completely removed the Br[−] (reduction from 6.3 at. % to 0.0 at. %) within the elemental quantification resolution limit of 0.4–1.0 at. % of the used XPS system, whereas after the O₂ plasma treatment some trace of Br[−] is still measurable (reduced from 6.3 at. % to 1.9 at. %) (Figure 2a and Table S1 for more detailed quantitative analysis). Most likely, the O₂ plasma removes the Br[−] of the outer layer of the bilayer (the one that does not bind to Pd) as illustrated in Figure 2a. As a second key point, analyzing the Pd 3d peaks for these three samples reveals the appearance of distinct “shoulders” in the spectrum after the O₂ plasma, which indicates significant surface oxidation of the Pd particles. Notably, these shoulders

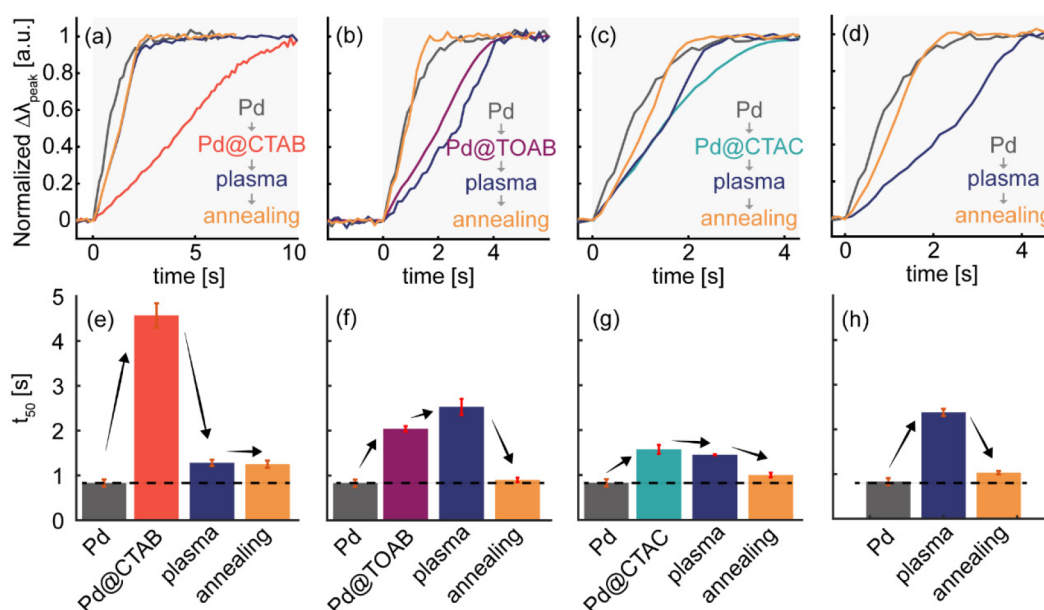

Figure 3. Temporal response of (a) Pd@CTAB, (b) Pd@TOAB, (c) Pd@CTAC, and (d) neat Pd to a stepwise 0 → 320 mbar H_2 pressure change at 30 °C before and after plasma-annealing treatments. The pressure change was executed at $t = 0$ s. The response was measured after (i) O_2 plasma → H_2 plasma (blue) and (ii) O_2 plasma → H_2 plasma → 250 °C annealing (yellow). t_{50} , that is, the time to reach 50% of the total normalized response for (e) Pd@CTAB, (f) Pd@TOAB, (g) Pd@CTAC, and (h) neat Pd, respectively. The error bars are the standard deviation obtained from three measurements. The arrows highlight the trend after each treatment step.

are absent both for the as-deposited Pd@CTAB sample and after H_2 plasma. This is expected due to the oxidizing and reducing nature of O_2 and H_2 plasma treatments, respectively. Hence, in principle, these findings would advertise H_2 plasma as the superior solution due to both its superior halogen species removing performance and benign properties with respect to inducing surface oxidation, that we also confirmed for Pd@TOAB (Figure 2c) and Pd@CTAC (Figure 2d; see the quantitative analysis in Table S1). Unfortunately, however, it has also been shown that H_2 plasma is inefficient for the removal of carbonaceous species, which in our present case translates to the alkyl tail(s) of the surfactant molecules.⁶⁰ Therefore, O_2 plasma in combination with H_2 plasma is necessary to remove the surfactant molecule completely. Furthermore, as the corresponding XPS analysis reveals for all three surfactants, subsequent O_2 plasma and H_2 plasma treatment ($O_2 \rightarrow H_2$) not only removes the surfactants but also leaves the Pd surface in its reduced metallic state (Figure 2b–d).

Having established this $O_2 \rightarrow H_2$ plasma cleaning scheme (below simply referred to as “plasma treatment”), it is now interesting to investigate its impact on the H_2 absorption rate for the Pd@CTAB, Pd@TOAB and Pd@CTAC systems, as well as an uncoated neat Pd control (Figure 3a–d). As observed previously,³² formation of the surfactant bilayer on the Pd significantly decelerates the H_2 absorption rate, with CTAB having the strongest deceleration effect, followed by TOAB and CTAC. As we have shown, this is the consequence of both (i) the surfactant packing density that hinders the H_2 diffusion to the Pd surface and (ii) the Br^- (or Cl^-) – Pd bond, which decreases the number of H_2 dissociation sites on the Pd surface.³² Accordingly, although both have identical Br^- counterions, TOAB is less densely packed on the Pd surface than CTAB due to its bulkier molecular structure, which explains TOAB’s more moderate deceleration effect compared to CTAB. On the other hand, although CTAC has a similar

packing density as CTAB in the bilayer, the deceleration effect is weaker because the Cl –Pd interaction is weaker than that of Br –Pd.^{39,42}

Having established the impact of the three different surfactants on the hydrogen absorption rate, we now assess the effect of subsequent plasma treatment. Evidently, plasma treatment of Pd@CTAB recovers its H_2 absorption rate, defined as t_{50} at which 50% of the signal change $\Delta\lambda_{peak}$ has occurred, from 4.6 to 1.3 s (Figure 3a, e). This is, however, still significantly slower than the absorption rate of the bare Pd measured on the same sample prior to applying the CTAB, i.e., 0.8 s (Figure 3e). Executing the same sequence of experiments on the Pd@TOAB (Figure 3b, f) and Pd@CTAC (Figure 3c, g) systems yields a very similar conclusion. Despite the complete removal of the surfactants by the plasma treatment confirmed by XPS, the original hydrogen absorption rate measured prior to surfactant deposition on each sample is not completely recovered. In fact, and even more intriguingly, plasma treatment further decelerates the hydrogen absorption rate of the Pd@TOAB system. Finally, we also note that we consistently make the same observations for the reversed process, i.e., hydrogen desorption (Figure S1).

To shed light on this surprising effect, we executed the same experimental sequence on a neat Pd sample that had never been exposed to any surfactant and found that also in this case plasma treatment significantly slows down the hydrogen absorption rate from $t_{50} = 0.8$ s to $t_{50} = 2.4$ s (Figure 3d, h). Hence, this observation indicates that plasma treatment instigates an additional effect on the system beyond surfactant removal. Interestingly, it is therefore only after 12 h of annealing at 250 °C in 4 vol % H_2 in Ar carrier that the absorption rates are almost completely recovered. In fact, the absorption rate recovers almost completely to the $t_{50} = 0.8$ s value of the pristine Pd, i.e., Pd@CTAB recovers to $t_{50} = 1.3$ s, Pd@TOAB recovers to $t_{50} = 0.9$ s, and Pd@CTAC recovers to $t_{50} = 1.0$ s (Figure 3 and Figure S1 for desorption).

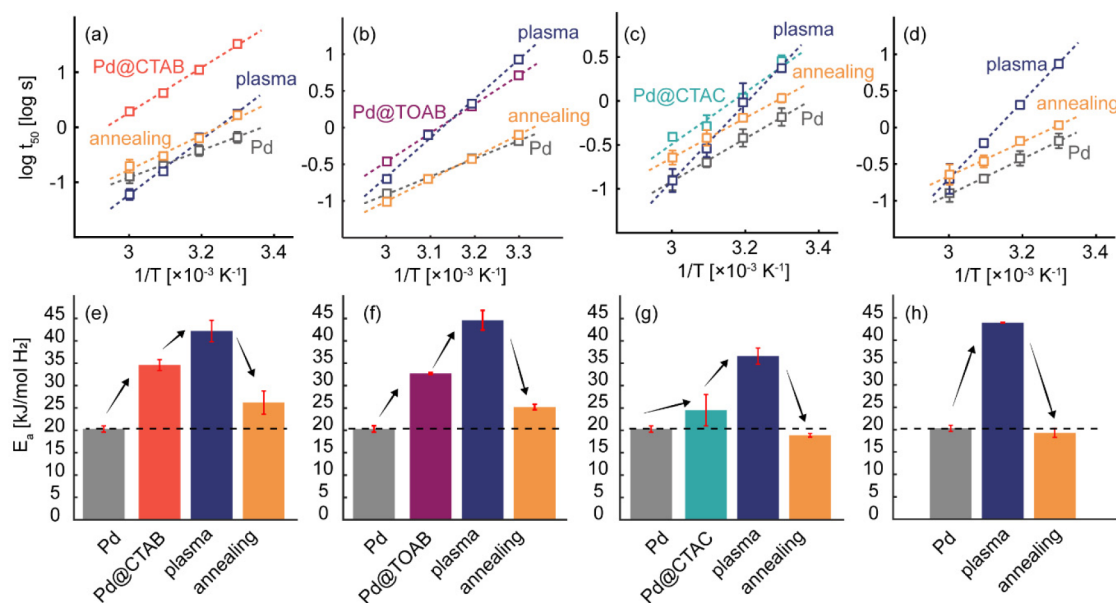

Figure 4. Hydrogen absorption Arrhenius plots for (a) Pd@CTAB, (b) Pd@TOAB, (c) Pd@CTAC, and (d) the neat Pd control, respectively, obtained by measuring the absorption kinetics at 30 °C, 40 °C, 50 °C, and 60 °C. The error bar in each data point denotes the standard deviation from three measurements. The absence of an error bar indicates that it is smaller than the symbol size. Apparent hydrogen absorption activation energy, E_a for (e) Pd@CTAB, (f) Pd@TOAB, (g) Pd@CTAC, and (h) the neat Pd control, calculated from the slope of the Arrhenius plots in a–d, respectively. The error bar denotes the linear-regression uncertainty of the Arrhenius plot. The arrows are guides to the eye that highlight the trend after each treatment step.

The distinct impact of the plasma treatment on the H_2 absorption kinetics is further manifested in the corresponding apparent activation energy, E_a , derived by Arrhenius analysis (Figure 4). Clearly, after plasma treatment, E_a increases by about a factor of 2 from 20.3 kJ/mol H_2 to 43.9 kJ/mol H_2 for neat Pd, to 42.2 kJ/mol H_2 for Pd@CTAB, to 44.6 kJ/mol H_2 for Pd@TOAB and to 36.6 kJ/mol H_2 for Pd@CTAC. Similar trends we also again observed for the reverse process of hydrogen desorption (Figure S2) and the annealing step recovers E_a to close to the initial value, i.e., to 19.3 kJ/mol H_2 for neat Pd, to 26.0 kJ/mol H_2 for Pd@CTAB, to 25.2 kJ/mol H_2 for Pd@TOAB, and to 18.9 kJ/mol H_2 for Pd@CTAC (Figure 4 and Figure S2 for desorption).

To investigate the reason causing this effect, we performed an XPS survey scan of a plasma treated Pd nanoparticle sample (never exposed to surfactants). This scan (Figure S3) reveals the presence of two unexpected species on the surface: Al and F (Figure 5). Both Al and F can be traced back to the plasma chamber (anode) since the chamber itself is comprised of aluminum and since the same chamber also is used for reactive ion etching using CF_4 . Since these species are not observed in the XPS scans of samples that we placed on a clean 4 in. Si wafer shield (Figure 5a) it is clear that the origin of Al and F on the samples indeed is the plasma chamber. Mechanistically, it can be understood as so-called swift chemical sputtering of these species by the H_2 plasma.⁶¹ Finally, we note that also the use of an Si wafer shield will not completely avoid surface contamination during H_2 plasma treatment since an XPS control measurement on an Au film sample that rested on the Si wafer shield during H_2 plasma treatment indeed shows Si contamination (Figure S4). As the main conclusion from this analysis, we note that, in principle, all measured contaminants might detrimentally influence H_2 sorption kinetics. However, among the found three species it is likely that F[−] contamination is the most relevant one due to its strong

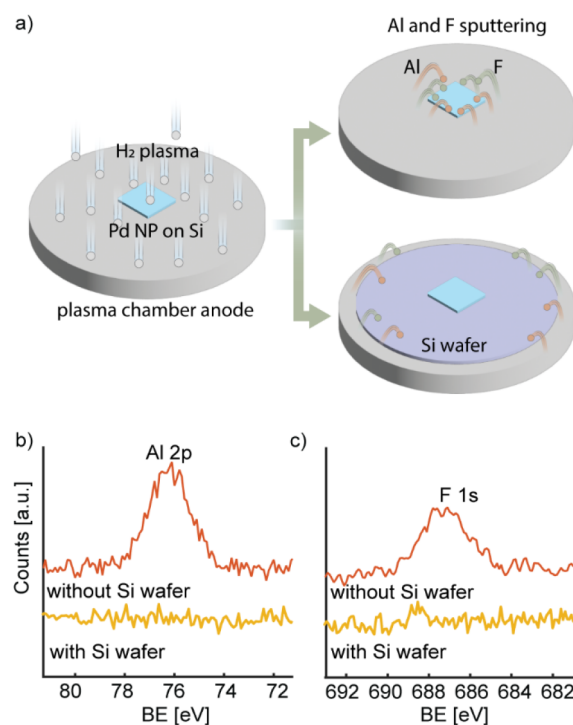

Figure 5. (a) Schematic depiction of the mechanism behind the secondary H_2 plasma sputtering of Al and F contamination onto the Pd nanoparticle sample from the aluminum plasma chamber (anode) and how it can be prevented by using a clean Si wafer as sample support (“shield”) during plasma treatment. We note that the F contamination has its origin from the plasma chamber that is also used for CF_4 reactive ion etching. High-resolution XPS spectra of the Al 2p (b) and F 1s (c) energy range revealing a distinct Al and F peak, respectively, and their absence when a Si wafer support was used during the plasma treatment.

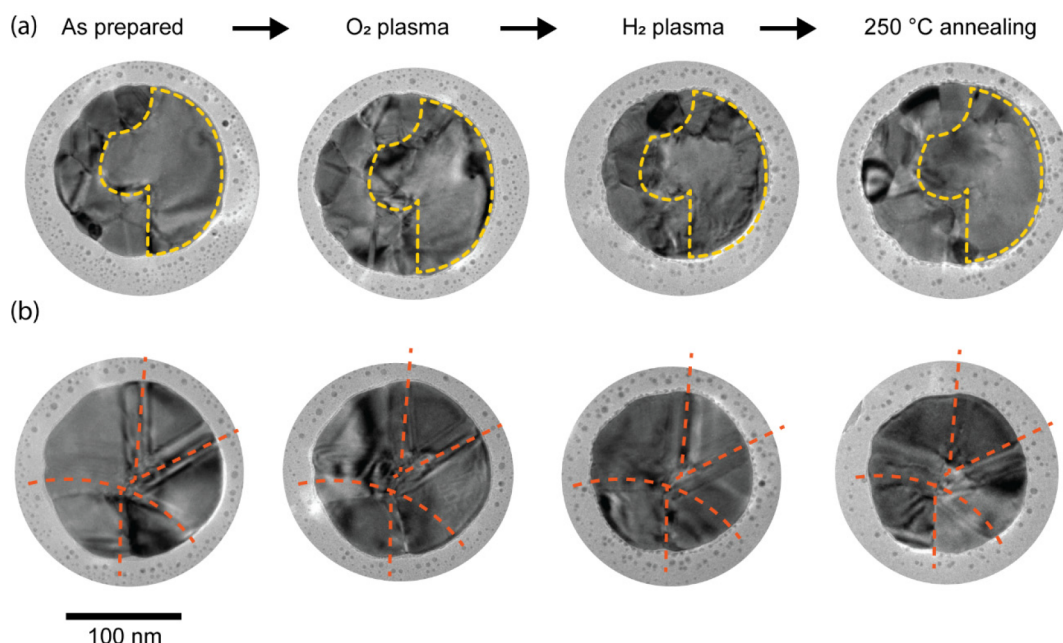

Figure 6. Transmission electron microscope images of two representative Pd nanoparticles taken (i) as prepared, (ii) after O₂ plasma, (iii) after H₂ plasma, and (iv) after 250 °C annealing. (a) Image sequence for nanoparticle #1 where the yellow dashed-line highlighted area indicates a region with significant surface roughness changes. (b) Image sequence for nanoparticle #2 where the red dashed lines signify grain boundaries. Note that the nanoparticle grain boundaries, shape, and size are virtually unchanged after the plasma and annealing treatments.

affinity to Pd, which is similar to other halides, such as Br[−] and Cl[−], which has been demonstrated to significantly slow down hydrogen sorption.³⁹

To also investigate potential structural reasons of the decelerated hydrogen sorption kinetics after plasma treatment, we took a series of intermittent transmission electron microscope (TEM) images along the entire plasma treatment sequence (Figure 6). The obtained images from two Pd particles reveal that particle size, shape and grain structure remain essentially unchanged, while the dark/bright regions slightly change (Figure 6a, b and Figure S5 for images of additional particles). Although TEM imaging is not a surface characterization technique, the observed evolution of the image contrast upon plasma treatment provides some insight into nanoparticle surface restructuring. Specifically, the darker regions might stem from high diffraction angles which can be inferred from induced strain or defects on the surface, as reported, for example, for lattice dislocations and stacking faults.^{62,63} This effect is particularly apparent after the H₂ plasma treatment step (Figure 6a, dashed-line highlighted region) and in line with earlier reports of plasma treatments structurally altering Pd surfaces at the atomic level.^{64,65} Furthermore, atomic force microscopy (AFM) topographical scans of representative nanoparticles corroborate the surface structuring as a significant increase of surface roughness from 0.1 ± 0.0 nm on a pristine Pd nanoparticle to 0.8 ± 0.0 nm after H₂ plasma treatment (Figure 7. For additional sampling details refer to Figure S6 and Table S3). This increasing surface roughness likely induces defects and thus local lattice strain. This is a relevant observation because it is well-known that E_a of hydrogen sorption in Pd is correlated with surface structure.^{23,58,66,67} Finally, the last TEM images in the sequence taken after the 12 h annealing at 250 °C in 4 vol % H₂ in Ar carrier gas reveal that a smooth particle surface reminiscent of the initial state can be recovered, while again

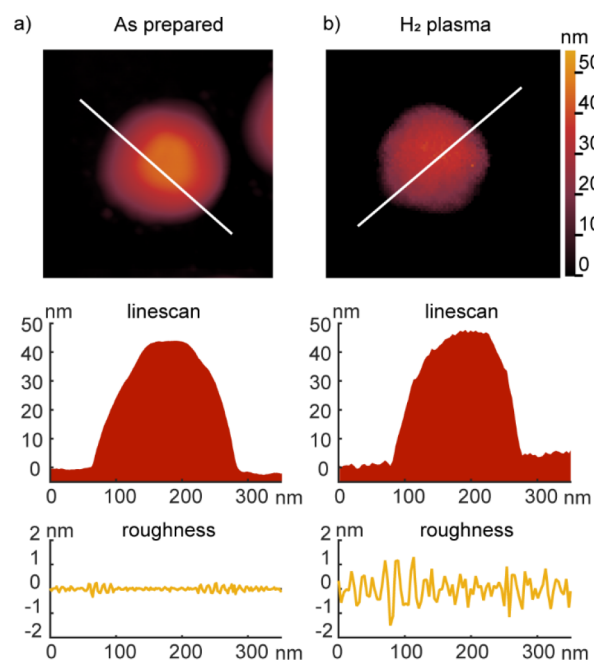

Figure 7. Atomic force microscopy (AFM) topography linescan and roughness analysis of representative Pd nanoparticles (a) as prepared and (b) after H₂ plasma treatment.

leaving particle size, shape and grain structure essentially unchanged (Figure 6a, b). It is worth noting that although the annealing induces a smoother surface, a precise recovery to the very initial state was not accomplished (compare the first and fourth columns of Figure 6).

Similarly, investigating the evolution of the Al and F contamination after 6 and 12 h of annealing using XPS reveals a distinct reduction of the F contamination over time from 4.6 to 0.5 at. % while leaving the Al concentration essentially

constant (Figure 8 and Table S2). Here we, however, note that Al is distributed homogeneously over the entire sample surface

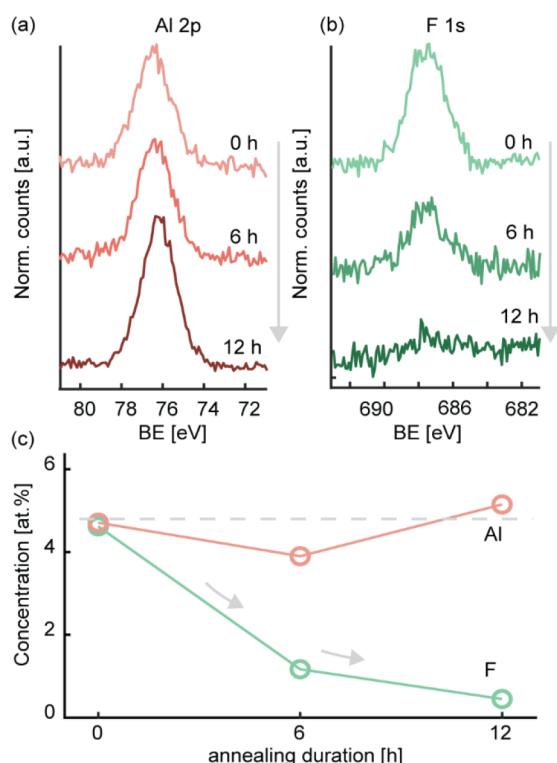

Figure 8. Time-evolution of high-resolution XPS spectra taken in the energy range of the (a) Al 2p and (b) F 1s peak. The spectra were taken directly after the sputtering sequence ($t = 0$ h) and after the Pd nanoparticles had been annealed for 6 and 12 h at 250 °C in 4% H₂ in Ar carrier gas. (c) Al and F surface concentration in at. % as determined from the XPS spectra in panels a and b plotted as a function of annealing time.

during the plasma cleaning. This means that it is also present in between the Pd nanoparticles on the substrate, an area that corresponds to approximately 90% of the sample surface due to the approximately 10% coverage of the Pd nanoparticles. Second, we note that Pd and Al form a solid solution in the relevant Al concentration regime,⁶⁸ which means that the Al contamination on the Pd is dissolved into the particles during the annealing. Since Al is present only in trace amounts from the beginning, its concentration in the solid solution in the Pd particles is so low that it very likely does not sizably affect the hydrogen sorption kinetics—in line with the observed almost perfect recovery. Consequently, the measured remaining Al XPS signal stems to the largest extent from the sample areas *between* the Pd nanoparticles where Al remains and likely also coalesces/sinters into tiny particles during the annealing, which may explain the slight variation in XPS signal.

CONCLUSIONS

We have developed an efficient cationic surfactant molecule removal strategy and illustrated it on the example of Pd nanoparticles. It comprises subsequent O₂ plasma and H₂ plasma treatments to remove the alkyl tail(s) and halide headgroups, respectively, as confirmed by high resolution XPS, followed by a gentle thermal annealing step to restore the surface state of the particles to preplasma conditions and to mitigate surface contamination from the plasma chamber

induced by the H₂ plasma cleaning step. We have demonstrated the validity of this approach by investigating the hydrogen sorption kinetics of the Pd nanoparticles along the entire process sequence, revealing significant slowing of the sorption process and apparent activation energy increase in the presence of surfactant molecules on the surface, as well as after plasma treatment when the surfactants have been removed. Only after the thermal annealing step the sorption rates and apparent activation energies are recovered to levels very similar to pristine Pd nanoparticles that had never been exposed to surfactant molecules and plasma treatment. This work thus advertises tailored plasma cleaning and mild heat treatments as effective recipe for the removal of surfactant molecules from nanoparticle surfaces. In a wider perspective, it also highlights the importance of both careful selection of plasma treatment(s) for the cleaning of nanoparticle and extended surfaces and detailed analysis of the impact of the cleaning procedure itself if, for example, the cleaned surfaces are to be used in surface reactions.

METHODS

Pd Particle Array Nanofabrication. Samples were fabricated onto flat surfaces using hole-mask colloidal lithography (HCL) following the procedures detailed elsewhere.^{69,70} As substrates we either used fused silica (for the LSPR sensing experiment), a thermally oxidized Si wafer (for XPS and SEM), or in-house fabricated⁷¹ TEM windows (for TEM imaging). In brief, the key steps of the nanofabrication procedure are (i) mask preparation via colloidal PS bead self-assembly, (ii) desired material deposition through the mask, and (iii) mask lift-off. The average diameter of Pd nanodisks targeted here was 190 nm and their thickness was 25 nm. After nanofabrication, the samples were all thermally annealed at 500 °C in 4% H₂ diluted in Ar (total flow 150 mL/min) for 24 h to induce a structurally stable state characterized by a high degree of crystallinity and particles comprising 5–10 crystallites. Notably, their diameter thereby shrinks to about 170 nm, while the thickness increases to ca. 40 nm due to recrystallization.

Surfactant Coating Procedures. Three types of surfactants, i.e., CTAB (cetrimonium bromide), CTAC (cetrimonium chloride), and TOAB (tetraoctylammonium bromide) were dissolved in Milli-Q (MQ) water at 10 mM concentration. The solution was then drop cast onto the nanofabricated Pd surfaces and covered with a glass lid for 24 h incubation.³² Subsequently, the excess surfactant solution was washed away in Milli-Q water and blow-dried with N₂ gas.

Transmission Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM). The TEM images were obtained using a Tecnai T20 microscope operating at 200 kV with LaB₆ filament electron gun. The SEM images were acquired using a Zeiss 60 VP operating at 10 kV electron beam energy with working distance of 5 mm.

Atomic Force Microscopy (AFM). Measurements were performed using a Dimension 3100 Scanning Probe Microscope from Bruker operated in tapping mode. The height scan was done over an area of 1 μm × 1 μm with height resolution 0.1 nm. To process the data (i.e., linescan plot and roughness calculation), the Gwyddion 2.48 software was employed.

Hydrogen Sorption Kinetics Measurements. The hydrogen sorption measurements were carried out in a vacuum chamber setup with optical windows reported elsewhere.⁷² The absolute hydrogen pressure in the chamber was monitored using two capacitive pressure gauges with different range pressure gauges (MKS Baratron). Optical transmittance through the sample was enabled by UHV-compatible fused silica windows mounted on the vacuum chamber, and by using a fiber-coupled, unpolarized white light source (Avantes AvaLight-Hal) and a fixed grating fiber coupled spectrophotometer (Avantes SensLine AvaSpec-2048XL). The temperature was controlled with a heating coil wrapped around the chamber and a temperature

controller (Eurotherm 3216) in a feedback loop manner, where the sample surface temperature inside the vacuum chamber was continuously used as input. We performed all our experiments at 30 °C. For the activation energy measurements, we measured sorption time traces of the sample at four different temperatures: 60, 50, 40, and 30 °C. The LSPR peak shift were obtained by Lorentzian fitting of the peak and extracting the spectral shift.

X-ray Photoelectron Spectroscopy (XPS). A PHI 5000 VersaProbe III (Physical Electronics) was used to confirm surfactant adsorption on the Pd nanoparticles and their removal, as well as to characterize contamination induced by the plasma cleaning process developed. The monochromatized $K\alpha$ X-rays of Al were used as excitation source. The high-resolution spectra were recorded with an energy step of 0.1 eV and a pass energy of 55 eV. The base pressure was $<5.0 \times 10^{-7}$ Pa. For surface concentration quantification the Multipak 6.0 software was used. The atomic concentration resolution is in the range of 0.4–1.0 at. %.

Plasma Cleaning Process. The plasma cleaning was done in a BatchTop m/95 PlasmaTherm Reactive Ion Etcher (RIE). Each cycle of the O_2 plasma cleaning recipe comprised 60 s exposure to 50 W, 250 mTorr, and 10 sccm and each cycle of the H_2 plasma cleaning recipe comprised 60 s exposure to 100 W, 250 mTorr, and 40 sccm H_2 plasma. For the final recipe, we applied two cycles of sequential O_2 plasma and H_2 plasma (as in $O_2 \rightarrow H_2 \rightarrow O_2 \rightarrow H_2$) to ensure the complete surfactant removal. It is worth noting that order matters: O_2 plasma induces oxidized Pd, and therefore the H_2 plasma is applied after the O_2 plasma to revert the oxidation.

Author Contributions

I.D., A.S., K.M.P., and C.L. designed the experiment. I.D. fabricated the Pd nanodisks. I.D. and C.L. wrote the manuscript. J.P. assisted with the manuscript writing. K.M.P. proof-read the manuscript. J.P. and A.S. prepared the surfactant deposition. I.D. performed the hydrogenation kinetics measurement. I.D. and J.P. performed the TEM imaging and analysis. I.D. performed the AFM measurement and analysis. C.T., C.A., and I.D. performed the XPS measurement and data analysis. C.L. coordinated the project.

Notes

The authors declare no competing financial interest.

■ ACKNOWLEDGMENTS

We acknowledge financial support from the Swedish Foundation for Strategic Research framework project RMA15-0052 (C.L.) and the Knut and Alice Wallenberg Foundation project 2016.0210 (C.L.) and the Wenner-Gren Foundation via contract UPD2020-0287 (J.P.). We thank Dr. Sara Nilsson for fruitful discussion of the TEM images. Part of this work was carried out at the Chalmers MC2 Cleanroom Facility and at the Chalmers Materials Analysis Laboratory (CMAL).
