Barium zirconate (BaZrO₃) is one of the very few perovskites that is claimed to retain an average cubic structure down to 0 K, while being energetically very close to an antiferrodistortive phase obtained by condensation of a soft phonon mode at the *R* point of the Brillouin zone boundary. In this work, we report a combined experimental and theoretical study of the temperature dependence of this soft phonon mode. Inelastic neutron and x-ray scattering measurements on single crystals show that it softens substantially from 9.4 meV at room temperature to 5.6 meV at 2 K. In contrast, the acoustic mode at the same *R* point is nearly temperature independent. The effect of the anharmonicity on the lattice dynamics is investigated nonperturbatively using direct dynamic simulations as well as a first-principles-based self-consistent phonon theory, including quantum fluctuations of the atomic motion are found to be important to obtain the proper temperature dependence at low temperatures. The mean-squared displacements of the different atoms are determined as function of temperature and are shown to be consistent with available experimental data. Adding anharmonicity to the computed fluctuations of the Ba-O distances also improves the comparison with available extended x-ray absorption fine structure data at 300 K.

I. INTRODUCTION

Perovskite oxides constitute a prominent class of materials with a wide range of different properties such as ferroelectricity, colossal magnetoresistance, electronic and/or ionic conductivity, piezoelectricity, superconductivity, metalinsulator transition, luminescence, and much more [1]. The ideal perovskite structure is cubic, with the general chemical formula ABO_3 , where the A and B sites can accommodate a wide variety of elements from the periodic table. Many perovskites are cubic at high temperatures but upon cooling most undergo one or several structural phase transitions, which depend sensitively on the choice of *A* and *B* [2,3]. This variety of compositions and structural phases yields the wide range of properties observed in these materials. The two most important structural distortions are the off-centering of the *B*-site cation, giving rise to ferroelectricity, and the tilts or rotations of the *BO*₆ octahedra [4]. The former is detectable as an instability at the Γ point in the Brillouin zone, while the latter are related to instabilities at the *R* and/or *M* points of the Brillouin zone boundary. To understand, predict, and control these structural distortions is a key issue in the research on perovskite oxides.

Barium zirconate $BaZrO_3$ (BZO) is a simple perovskite that has attracted considerable interest due to its excellent thermal stability, high melting temperature, low thermal expansion coefficient, low dielectric loss, and low thermal conductivity [5]. These properties make BZO highly attractive for a range of technological applications such as wireless communication [6], thermal barrier coatings for gas turbines [7], protonic fuel cell applications [8] and ceramic reactors [9], as well as substrates in thin-film deposition [10].

Barium zirconate (BZO) is also one of the very few perovskites that is claimed to remain cubic down to 0 K, but its

tendency towards an antiferrodistortive instability has fueled a lot of studies and debates about its ground state, its average structure, and the possibility for local disorder. Several firstprinciples calculations, based on the density functional theory (DFT), predict the cubic structure to be unstable at 0 K, due to a soft phonon mode at the R point of the Brillouin zone corresponding to antiphase tilts of sequential oxygen octahedra, i.e., an antiferrodistortive mode [11-16]. However, the DFT results are sensitive to the exchange-correlation functional [17] and by using hybrid functionals a stable cubic structure is obtained at 0 K [17,18]. It has been suggested that, in cases where the instability, as observed in the DFT calculations, is weak, quantum fluctuations may suppress the phase transition in BZO and the material therefore stays cubic all the way down to 0 K [11,13,15]. Experimentally, both x-ray and neutron diffraction data on a powder sample, suggest a cubic structure down to T = 2 K [13], which is further supported by Raman spectroscopy on a single crystal [19]. On the other hand, a recent study combining electron diffraction with total neutron scattering measured on ceramic samples claimed that the material underwent a structural change below 80 K associated with the onset of correlated tilts of ZrO_6 octahedra [20].

Clearly, direct measurements and theoretical modeling of the tilt mode frequency and its temperature dependence are essential for a good understanding of BZO. Experimentally, direct lattice dynamical studies have been limited by the scarcity of suitable large and high-quality single crystals, as their synthesis is made difficult by the very high melting point of BZO. As a result, the only experimental study of the temperature dependence of the *R*-tilt mode of BZO has been attempted on a polycrystalline sample [17]; it concluded that the tilt mode lies at 5.9 meV at low temperatures and does not exhibit any significant temperature dependence between 5 and 500 K. Recently, high-quality BZO single crystals have been synthesized using the floating-zone technique [21]. Here we take advantage of those single crystals to investigate directly the low-frequency lattice dynamics.

Quantitative theoretical modeling of the temperature dependence of the low-frequency vibrational motion of BZO is challenging. In recent years several methods have been developed to treat vibrational anharmonicities for solids, such as the self-consistent *ab initio* lattice dynamics (SCAILD) technique [22], the temperature-dependent effective potential (TDEP) method [23], and the stochastic self-consistent harmonic approximation (SSCHA) [24]. Methods based on the selfconsistent phonon approach [25] have also been developed by Tadano *et al.* [26], which implements the Green's function technique to derive the anharmonic contributions. Recently, this latter technique was used to study anharmonicity-induced phonon hardening and thermal transport in BZO in the temperature range 300–2000 K [27].

Here, a force constant potential (FCP), expanded up to fourth order, is derived based on training structures from density functional theory (DFT) calculations and by making use of regression techniques [28]. The FCP takes anharmonicity into account and it is used in molecular dynamics (MD) simulations [29,30] to capture the full dynamical structure factor and its temperature dependence [31]. A selfconsistent phonon (SCP) approach is then implemented [28] to, in addition to anharmonicity, also include the quantum fluctuations of the atomic motion, known to be significant at low temperatures [13].

The paper is organized as follows. In Sec. II the theoretical methods used to treat the anharmonic lattice vibrations are introduced, including the effect of the quantum fluctuations of the atomic motions at low temperatures. Section III presents the experimental data obtained by inelastic neutron and x-ray scattering that reveal the strong softening of the tilt mode and the comparatively temperature-independent behavior of the acoustic mode. In Sec. IV, the theoretical results are presented and compared with our experimental data. The strong temperature dependence of the soft tilt mode is found to be in quantitative agreement with our theoretical predictions and the obtained essentially temperature-independent acoustic mode also agree with the theoretical predictions. In Sec. V it is shown that our theoretical results for the atomic displacements agree favorably with available experimental data for the mean-squared displacements as well as with the more local information obtained in extended x-ray absorption fine structure (EXAFS) spectroscopy. Finally, Sec. VI discusses our present theoretical results and puts them into a broader context and Sec. VII summarizes our main conclusions.

II. THEORETICAL METHODS

A. Density functional theory

The DFT calculations are carried out using the Vienna *ab initio* simulation package (VASP) [32,33].

The potential energy surface (PES) for the R-tilt mode depends quite sensitively on the exchange-correlation functional [17]. The local density approximation (LDA), two generalized gradient approximations (PBE [34] and PBEsol [35]), as well as a functional including nonlocal correlation effects (CX) [36,37] all give a double-minimum PES for the *R*-tilt mode coordinate using the experimental value for the lattice constant. Using the corresponding theoretical lattice constants, LDA gives deeper potential minima, while for PBE the double-minimum feature disappears. Two hybrid functionals (HSE [38,39] and CX0p [40]) show in general better agreement for the various vibrational frequencies and both show an anharmonic PES for the R-tilt mode, quite similar to PBE at its theoretical lattice constant. The computational cost for the hybrid functionals is substantial compared with generalized gradient approximations and as a compromise between accuracy and computational cost we have therefore chosen to base this study on PBE using its theoretical lattice constant. For comparison, PBEsol has also been used, and the corresponding results are presented in Sec. VI.

The included projector-augmented wave (PAW) [41,42] potentials are used with energy cutoff 500 eV. The considered valence configurations for Ba, Zr, and O are $5s^25p^66s^2$, $4s^24p^64d^25s^2$, and $2s^22p^2$, respectively. The Brillouin zone of the primitive cell is sampled with an $8 \times 8 \times 8$ Monkhorst-Pack *k*-point mesh and scaled accordingly for larger cells. The obtained lattice constants for PBE and PBEsol are *a* = 4.236 and 4.192 Å, respectively.

The nonanalytic part of the dynamical matrix, which is due to the long-range dipole-dipole interaction [43,44], is evaluated and applied in calculating the phonon dispersion relations using PHONOPY [45]. The values for the dielectric tensor ε and Born effective charges Z^* are computed to be $\varepsilon = 4.87$, $Z^*(Ba) = 2.72$, $Z^*(Zr) = 6.11$, and $Z^*(O)_{\parallel} = -4.85$ and $Z^*(O)_{\perp} = -1.99$ for the two different displacement directions of the oxygen ion.

B. Force constant potential

The force constant potential is based on an expansion of the potential energy U in terms of atomic displacements u_i^{α} from their equilibrium positions \mathbf{R}_i^0 . We consider an expansion up to fourth order

$$U = U_0 + \frac{1}{2!} \Phi_{ij}^{\alpha\beta} u_i^{\alpha} u_j^{\beta} + \frac{1}{3!} \Phi_{ijk}^{\alpha\beta\gamma} u_i^{\alpha} u_j^{\beta} u_k^{\gamma} + \frac{1}{4!} \Phi_{ijkl}^{\alpha\beta\gamma\delta} u_i^{\alpha} u_j^{\beta} u_k^{\gamma} u_l^{\delta}, \qquad (1)$$

where the Φ 's are referred to as force constants (FCs). Latin indices run over atomic labels, greek over Cartesian coordinates, and Einstein summation applies. First, an initial phonon calculation is carried out for a 3 × 3 × 3 supercell (135 atoms) using DFT. These phonons are used to construct a set of training structures with displacements generated via populating the normal modes with different temperatures. These structures are used to construct an initial fourth-order force constant potential (FCP) using HIPHIVE [28].

Next, the size of the system is increased to a $4 \times 4 \times 4$ supercell (320 atoms). The initial fourth-order FC model is used to run molecular dynamics (MD) simulations carried out at 10, 150, 300, and 500 K. Snapshots from these simulations together with some small amplitude structures along the Rtilt mode are used as training structures for the final model. For the final model, we considered two- and three-body interactions up to, and including, the fourth order. We used a maximum interaction length of 8 Å for the harmonic force constants. Whereas, for the anharmonic interactions, that is, the third- and fourth-order interactions, we set a maximum interaction length for the force constants to 5 Å. The training was carried out using the recursive feature elimination method [46]. We denote this final model as the force constant potential (FCP) model. The accuracy of the FCP is evaluated using cross validation (CV), and an average root-mean-square error (RMSE) of 0.034 eV/Å is obtained over the validation set. For the CV plot, see Fig. S1 in Supplemental Material [47].

C. Harmonic phonon model

By truncating the FCP model at the second-order term an harmonic approximation is obtained. We will denote this the *harmonic phonon (HP)* model. Within the harmonic approximation eigenfrequencies $\omega_{q,v}$ and eigenvectors $e_{q,v}$ can be derived [45]. Here, q is the wave vector and v the band index. In Fig. 1 we show the phonon dispersion for BZO using the HP model and where the correction due to the long-range dipole-dipole interaction [43,44] has been applied. At the *R* point the lowest branch at 3.8 meV corresponds to antiphase tilts of sequential ZrO₆ octahedra. This will here be denoted the *R*-tilt mode. The second lowest branch located at 12.1 meV at the *R* point is the acoustic branch due to barium displacements, here denoted the *R*-acoustic mode.

FIG. 1. Phonon dispersion relations within the harmonic model (the HP model) for BZO using PBE. Color assigned as (Ba, Zr, O) = (red, green, blue).

The phonon dispersions in Fig. 1 are similar to what is obtained from the standard small displacement method (for a comparison, see Fig. S2 in Supplemental Material [47]). However, the *R*-tilt mode frequency is sensitive to the theoretical treatment due to anharmonicity. Here, we have developed a harmonic model based on displacements from MD simulations carried out at 10, 150, 300, and 500 K. The obtained *R*-tilt mode frequency is 3.8 meV, slightly larger than 2.7 meV, obtained using the standard small displacement method with the default displacement ± 0.01 (see Fig. S2 in Supplemental Material [47]).

The PES along the R-tilt mode is shown in Fig. 2. The FCP model agrees very well with the DFT data. In contrast, the HP approximation deviates markedly from the DFT data, demonstrating that the R-tilt mode is strongly anharmonic.

Within the harmonic approximation the temperaturedependent atomic displacement of atom *i* in direction α , u_i^{α} , is given by a Gaussian distribution with mean value zero and

FIG. 2. The potential energy surface (PES) along the *R*-tilt mode based on PBE. The fourth-order FCP model agrees very well with the DFT data, while the second-order model, the HP model, deviates markedly.

variance

$$\left\langle \left(u_{i}^{\alpha}\right)^{2}\right\rangle = \frac{1}{N_{q}}\sum_{\boldsymbol{q},\nu}\frac{\hbar}{2m_{i}\omega_{\boldsymbol{q},\nu}}\left|e_{\boldsymbol{q},\nu}^{i,\alpha}\right|^{2}\coth\left(\hbar\omega_{\boldsymbol{q},\nu}/2k_{\mathrm{B}}T\right).$$
 (2)

Here, $\langle ... \rangle$ denotes a thermal average, m_i is the mass of atom i, and N_q the number of q values in the summation.

D. Self-consistent phonon model

In the *self-consistent phonon (SCP)* model, a temperaturedependent effective harmonic model is constructed. We start with the harmonic model. Displacements u_i^{α} are generated in a supercell using the Box-Muller method according to

$$u_i^{\alpha} = \sum_{\lambda} A_{\lambda}^i e_{\lambda}^{i,\alpha} \sqrt{-2 \ln U_{\lambda}} \cos\left(2\pi Q_{\lambda}\right), \tag{3}$$

where the index $\lambda = (q, \nu)$ enumerates the points commensurate with the supercell, and U_{λ} and Q_{λ} are uniform random numbers on [0,1]. The temperature-dependent amplitude A_{λ}^{i} is given by the standard deviation of the displacements [cf. Eq. (2)]

$$A_{\lambda}^{i} = \sqrt{\hbar \coth \left(\hbar \omega_{\lambda} / 2k_{\rm B}T\right) / (2m_{i}\omega_{\lambda})}.$$
 (4)

Using Eq. (3) a set of displacements **u** is generated at a chosen temperature T and the corresponding forces are calculated using the FCP. We generate M such reference structures. The generated displacements and forces are encoded in the fit matrix $\mathbf{A}(\mathbf{u})$ and the force vector $\mathbf{f}(\mathbf{u})$, respectively. An effective harmonic model is obtained by solving the minimization problem

$$\min \|\mathbf{A}(\mathbf{u})\mathbf{x} - \mathbf{f}(\mathbf{u})\|, \tag{5}$$

where \mathbf{x} are the free parameters of effective harmonic model. The procedure is iterated until convergence

$$\mathbf{x}_{n+1} = (1 - \alpha) \, \mathbf{x}_n + \alpha \min_{\mathbf{x}} \|\mathbf{A}(\mathbf{u}_n)\mathbf{x} - \mathbf{f}(\mathbf{u}_n)\|, \qquad (6)$$

where \mathbf{u}_n is a set of displacements generated with the *n*th effective harmonic model (\mathbf{x}_n) and α is a suitable chosen parameter to obtain efficient numerical convergence [28]. A self-consistent effective harmonic model at temperature *T* is then obtained.

The above procedure is repeated at different temperatures and temperature-dependent eigenfrequencies and eigenvectors are obtained.

III. EXPERIMENTAL METHODS AND RESULTS

A. Experimental details

BaZrO₃ single crystals were grown by the optical floatingzone technique as described in Ref. [21]. A single crystal was extracted from the boule for inelastic neutron scattering (INS) measurements with irregular shape and some natural facets suitable for sample orientation, with a total mass of approximately 200 mg and a size of a few millimeters. The sample for inelastic x-ray scattering (IXS) was cut from another smaller piece and thinned down to a lamella of approximately 50 m in thickness.

FIG. 3. Inelastic neutron scattering (INS) spectra measured at the R point (0.5 0.5 2.5) between 296 and 2 K, showcasing the softening of the lowest-energy mode.

INS spectra were measured on the IN8 high-flux thermal neutron triple-axis spectrometer [48] at Institut Laue Langevin (ILL) [49]. The initial and final neutron energies were selected using a doubly focused Cu (200) monochromator and analyzer, which resulted in an energy resolution of 0.62 meV as measured at the elastic peak. A pyrolytic graphite filter was placed in front of the analyzer to suppress higher-order neutrons. Measurements were performed at a fixed scattered wave vector $k_f = 2.662 \text{ Å}^{-1}$. Due to the reduced size of the crystal, no collimation could be installed without excessive loss in intensity. A preliminary test experiment was also previously carried out on the triple-axis spectrometer IN22 at the ILL with similar but more limited results [50].

IXS measurements were performed on the ID28 beam line at the European Synchrotron Radiation Facility (ESRF), as described in Refs. [51,52]. For this experiment, the (999) Bragg reflection of a Si crystal was used to analyze the scattered beam, giving rise to an energy resolution $\Delta E = 3.0 \pm 0.2$ meV.

B. R-point data from INS

Phonon spectra at the R point (0.5 0.5 2.5) were measured by INS at different temperatures and the results are presented in Fig. 3. The spectra display two peaks at every temperature between 296 to 2 K. The low-frequency peak shows a clear softening accompanied by an increase of the asymmetry of the peak, while the higher-frequency peak is essentially temperature independent in the considered temperature interval.

By comparing with DFT calculations and the calculated phonon dispersions in Fig. 1 the low-frequency peak can be attributed to the antiphase oxygen tilt oscillations, the *R*-tilt mode, while the higher-frequency peak corresponds to the acoustic branch and is connected to barium displacements, the *R*-acoustic mode. We also checked that the *R*-tilt mode vanishes at the *R* point (1.5 1.5 1.5) while the *R*-acoustic mode is still present, which is consistent with the neutron selection rules expected for modes of R_4^+ et R_5^+ symmetry, respectively [49].

INS spectra of BaZrO₃ are proportional to the neutron coherent cross section: $(\bar{b})^2 \frac{k_f}{k_i} S(Q, E)$, where *b* is the nuclear scattering length, k_i (respectively k_f) the wave vector of the incident (respectively scattered) neutron beam, and S(Q, E) the neutron scattering function. For oxygen and barium, the coherent scattering lengths are quite similar ($b_0 = 5.803$ fm and $b_{Ba} = 5.07$ fm) while zirconium has a higher one ($b_{Zr} = 7.16$ fm) [53]. Hence, for given k_i and k_f and with the proper selection rules, neutron intensity should be of the same order of magnitude for the oxygen-dependent *R*-tilt and the barium-dependent *R*-acoustic modes.

Aside from the pronounced softening, the *R*-tilt mode shows a strong asymmetric shape. We assume that this is due to the strong dispersion of the phonon branch close to the *R* point. The increase of the phonon frequency away from the *R* point implies that the measured peak may obtain an asymmetric shape towards higher frequencies. Anharmonicity also contributes to the broadening of the *R*-tilt mode but that broadening is more symmetric in frequency and increases with temperature (cf. Fig. 6). Nanodomains, proposed in Ref. [20], could arguably affect the mode damping and the spectrum in general, although in the present state, our data do not really provide evidence for or against the presence of these domains.

The neutron scattering data were then fitted with a sum of damped harmonic oscillators using the TAKIN [54–56] software, taking into account the instrumental resolution (see Fig. S4 in Supplemental Material [47]). In order to account for the asymmetric shape of the *R*-tilt mode, a first fitting was attempted by assuming a parabolic dispersion. This, however, did not allow us to obtain a satisfactory fit. We therefore introduced a more *ad hoc* mathematical asymmetry to the line shape. This allows us to extract values for the mode energy, but does not allow to deconvolute fully the spectrum and get access to the intrinsic widths. With this data treatment, we observe a softening of the *R*-tilt mode from 9.4 meV at 296 K to 5.6 meV at 2 K. The *R*-acoustic mode stays essentially constant around an average value of 13.0 meV.

The strong temperature dependence of the *R*-tilt mode contrasts with the inelastic scattering data previously reported by Perrichon *et al.* [17] on a *powder* sample. At low temperatures, 5 K, they obtained the frequency 5.8 meV, in very good agreement with our result. However, essentially no temperature dependence could be seen in the interval from 5 to 500 K. The present single-crystal study allows us to observe and quantify the temperature dependence more accurately.

C. R-point data from IXS

The phonon spectra at the R-point were also measured by IXS at different temperatures and the result is presented in Fig. 4. At each temperature between 300 to 80 K the spectrum displays a central quasielastic peak and two peaks respectively linked to the *R*-tilt mode and the *R*-acoustic mode, which can be both seen at positive and negative frequencies, due to

FIG. 4. Inelastic x-ray scattering (IXS) spectra measured at the R point (0.5 0.5 3.5) between 300 and 80 K. Both Stokes and anti-Stokes peaks are represented. We observe the softening of the R-tilt mode. The R-acoustic mode is barely temperature dependent.

Stokes and anti-Stokes scattering processes. Here, in contrast to the INS measurement, the *R*-tilt mode involving oxygen motion appears much weaker than the acoustic mode that is dominated by barium displacements. The IXS spectra were fitted by the sum of two damped harmonic oscillators and a Lorentzian for the pseudoelastic contribution. The *R*-tilt mode frequencies softens from 8.3 meV at 300 K to 5.2 meV at 80 K. The *R*-acoustic mode stays essentially constant around an average value 13.4 meV. The widths of the modes are in all cases resolution limited and do not show any physically insightful trend.

D. Dispersion data from INS and IXS

To reconstruct phonon dispersions, we have also measured spectra away from the R point, in the directions $R(0.5\ 0.5\ 2.5)$ - $M(0.5\ 0.5\ 2)$ and $R(0.5\ 0.5\ 2.5)$ - $\Gamma(1\ 1\ 2)$ at 2 K for INS. For IXS, we measured in the directions $R(0.5 \ 0.5 \ 3.5) - M(0.5 \ 0.5 \ 0.5)$ 4) and $R(0.5 \ 0.5 \ 3.5) - \Gamma(1 \ 1 \ 4)$ at 80 K. When both *R*-tilt and R-acoustic modes were resolved, INS spectra were fitted as previously. However, further from R, it becomes very difficult to resolve two peaks as the *R*-tilt mode broadens and crosses the R-acoustic mode. Then, spectra were fitted by a singledamped harmonic oscillator to extract the frequency of the *R*-acoustic mode. For the IXS experiments, spectra were fitted as previously by a sum of damped harmonic oscillators for the R-tilt mode and R-acoustic mode, and by a Lorentzian line shape for the pseudoelastic peak centered around 0 meV. In some spectra, higher-frequency features appear above 20 meV and up to the edge of the frequency range ($\approx 30 \text{ meV}$). When these features are present, they have been fitted by additional damped harmonic oscillators.

Frequencies extracted from the fits of INS and IXS spectra are represented in Fig. 5. The spectra and their fits are given in Figs. S5 and S6 in the Supplemental Material [47]. We

FIG. 5. Measured dispersion curves along the Γ -*R*-*M* path, measured at 2 K by inelastic neutron scattering (INS) and at 80 K by inelastic x-ray scattering (IXS). For experimental data, error bars are the width of the fitted peak (INS) or the instrumental resolution (IXS). Open symbols indicate data points that we could not identify by comparison to phonon calculations.

can first observe that the frequency of the *R*-acoustic mode is very consistent between the INS and IXS measurements, the difference in temperature for the two measurements being here negligible. The *R*-acoustic mode reaches its maximum frequency of around 13 meV at the *R* point. This frequency then decreases towards Γ and tends towards a value of around 11 meV at the *M* point.

The *R*-point soft mode is at its lowest energy at R (in INS \approx 5.6 meV, in IXS \approx 5.2 meV) and rises quickly in energy as we probe further from R. While the spectra are particularly unambiguous at the R point itself, the picture becomes much less clear as we move away from the zone boundary. Along the R-M direction, we observe a single branch attributed to oxygen, whereas phonon band calculations and symmetry considerations predict a splitting into two oxygen branches (see Fig. 1). The tilt modes at M also could not be identified with certainty. This is because the lowest tilt mode at M (with M_3^+ symmetry) as well as the branch (T_4) connecting that mode to the tilt mode at R are indeed forbidden by symmetry for our measurement configuration with Q from (0.5 0.5 2.5) to (0.5 0.5 2.0). Further experiments in a less symmetric configuration assisted with accurate calculations of scattering cross sections will be needed to clarify the modes at M and the dispersion along the *R*-*M* direction.

In addition, in the IXS data we observe extra modes at higher frequencies (above 20 meV, shown in open symbols on Fig. 5) both in the middle of the *R*- Γ direction and in the *R*-*M* direction. The energies of the modes on the *R*-*M* direction agree very well with the Zr-dominated (green) phonon branch seen in Fig. 1, and the high intensity of the IXS peaks also points to a mode involving a heavy atom. The mode along Γ -*R* on the other hand is much weaker (see Fig. S6 in Supplemental Material [47]) and difficult to assign conclusively. This mode might be of spurious origin and further studies will be necessary to clarify its assignment. This is inconsequential for our low-frequency study of the *R*-tilt mode and acoustic mode.

FIG. 6. The temperature dependency of the dynamical structure factor $S(q, \omega)$ at the *R* point $[q = (2\pi/a)[0.5, 0.5, 2.5]]$ from MD simulations using the force constant potential (FCP) model based on PBE.

IV. THEORETICAL RESULTS AND COMPARISON

A. Dynamical structure factor

The FCP potential can be used to perform MD simulations. The full anharmonicity in Eq. (1) is taken into account but the motion is restricted to classical dynamics.

We consider an $8 \times 8 \times 8$ supercell (N = 2560 atoms) with periodic boundary conditions and the MD simulations are carried out using the GPUMD [30] package with the FCP [57]. The system is equilibrated in the NVT ensemble using the Langevin thermostat and the positions $\mathbf{r}_i(t) = \mathbf{R}_i^0 + \mathbf{u}_i(t)$ are then sampled in the NVE ensemble using the velocity Verlet algorithm. The total simulation time is set to 2 ns with a time step of 1 fs.

The intermediate scattering function

$$F(\boldsymbol{q},t) = \frac{1}{N} \sum_{i}^{N} \sum_{j}^{N} \langle b_{i}b_{j}\exp\{i\boldsymbol{q}\cdot[\boldsymbol{r}_{i}(t)-\boldsymbol{r}_{j}(0)]\}\rangle$$
(7)

is determined at the *R* point, for the wave vector $q = (2\pi/a)[0.5, 0.5, 2.5]$, as a time average $\langle \dots \rangle$ using DYNASOR [31]. The nuclear scattering lengths b_i are given in Sec. III. The dynamic structure factor

$$S(\boldsymbol{q},\omega) = \int_{-\infty}^{\infty} F(\boldsymbol{q},t) \exp(-i\omega t) dt$$
(8)

is then obtained by a Fourier transformation and $S(q, \omega)$ is averaged over 50 independent MD simulations with different initial velocities.

The resulting dynamical structure factor, as function of temperature, is shown in Fig. 6. Two set of peaks are seen. One at lower frequencies, from 4 to 9 meV, and one at higher frequencies, between 12 and 13 meV. The lower-frequency mode corresponds to oxygen motion, the *R*-tilt mode. It shows a strong temperature dependence, and the peak broadens as temperature increases. The peaks at higher frequencies correspond to motion of barium, the *R*-acoustic mode. A weak temperature dependence is observed, indicating that this vibrational motion of barium is associated with a weak

FIG. 7. The phonon dispersion at different temperatures obtained from the self-consistent phonon (SCP) model based on PBE.

anharmonicity. In order to extract the frequencies, we fit the spectra to a damped harmonic oscillator model (see Supplemental Material [47]). The obtained theoretical frequencies are compared with our experimental data points in Fig. 8.

B. Dispersion relation

Next, we consider the self-consistent phonon (SCP) method. The model is based on a $6 \times 6 \times 6$ supercell, and we use M = 80 structures in each iteration. The minimization in Eq. (5) is solved by ordinary least squares (OLS) and the iteration in Eq. (6) is stopped once the free energy for the effective harmonic system is smaller than 0.001 meV per atom for two successive iterations.

In Fig. 7 part of the resulting phonon dispersion for five different temperatures is shown. The oxygen-related *R*-tilt mode is clearly temperature dependent, and the barium related *R*-acoustic mode shows only a weak temperature dependence.

At the *R* point we observe a softening of the *R*-tilt mode from 9.0 meV at 300 K to 5.6 meV at 0 K. Also at the *M* point the softening is substantial, from 13.5 to 11.4 meV in the same temperature range. The *R*-acoustic mode is nearly constant with temperature. At the *R* point the frequency decreases slightly, from 12.8 to 12.4 meV in the temperature range 300 to 0 K. The obtained theoretical frequencies are compared with our experimental data points in Figs. 8 and 9.

C. Comparison between theory and experiments

Our key result is the temperature dependence of the antiferrodistortive phonon mode, the *R*-tilt mode. In Fig. 8 we compare our experimental and theoretical results for both the *R*-tilt mode and the *R*-acoustic mode.

The *R*-tilt mode shows a strong temperature dependence. From the INS data we obtain a softening from 9.4 meV at 296 K to 5.6 meV at 2 K, while the IXS data decrease from 8.3 meV at 300 K to 5.2 meV at 80 K. The INS frequencies are therefore consistently higher by about 1 meV, compared with the IXS frequencies. The two data sets agree within experimental uncertainties, but we consider the INS data to be more reliable since the *R*-tilt mode is weak in the IXS spectra. Our theoretical results, the data based on the

FIG. 8. The temperature dependency for the *R*-tilt and *R*-acoustic modes, both from experiments (INS and IXS) and theory (SCP and MD). HP is the harmonic approximation, which is temperature independent. The theoretical data are based on PBE. For experimental data, error bars are the width of the fitted peak (INS) or the instrumental resolution (IXS).

self-consistent phonon (SCP) method and the result obtained using the dynamic simulation technique (MD), agree nicely with the experimental data.

Theory predicts that below about 100 K the quantum fluctuations of the atomic motion become important in sampling the configuration space (cf. Fig. 12). It implies that the change of the frequency, the slope, decreases when approaching 0 K from above. This is seen in the experimental INS data, while the IXS measurements do not reach sufficiently low temperatures to observe this effect. The quantum fluctuations are included in the SCP method and the corresponding data show a clear decrease of the slope. In the MD method, the dynamics is treated classically (does not contain the quantum fluctuations) and the corresponding data show an increase of the slope when approaching 0 K from above, in contrast to the SCP data.

At higher temperatures, above 100 K, the *R*-tilt mode is well described by classical sampling and thus the difference between MD and SCP seen in Fig. 8 comes from the differences between these two computational techniques. In the MD technique all anharmonicities within the given FCP are included while in the SCP method the configuration space is sampled by independent normal modes, based on an effective harmonic model which has been computed using the same FCP as in MD. It has been argued that using noninteracting normal modes could potentially lead to sampling of higher-energy structures by the SCP method. This would then result in higher effective vibrational frequencies [58]. Therefore, we expect the MD method to be more accurate compared with the SCP method at higher temperatures.

For comparison, the results using the effective harmonic model introduced by Hellman *et al.* [23] have also been computed. This model is based on samples from a classical

FIG. 9. The dispersion curves for the *R*-tilt and *R*-acoustic modes, both from experiments (INS and IXS) and theory (SCP), and at two different temperatures, about 0 and 100 K. The theoretical data are based on PBE. For experimental data, error bars are the width of the fitted peak (INS) or the instrumental resolution (IXS).

MD trajectory and thus lacks the quantum fluctuations of the atomic motion. In the present case, it gives very similar results as the MD model for the temperature dependence of the *R*-tilt mode. For more details, see Fig. S8 in the Supplemental Material [47].

In Fig. 8 we also show the temperature dependence of the R-acoustic mode, located at about 13 meV. It shows a very weak temperature dependence. The IXS data decrease with about 0.4 meV when reducing the temperature from 300 down to 80 K, while the INS data are essentially temperature independent. A small decrease is also obtained using the SCP and MD methods, about 0.5 meV. In this case the two theoretical methods give very similar results for the frequencies. The theoretical data are based on PBE and are about 1 meV lower than the experimental result. However, it is known that the more accurate hybrid functionals HSE and CX0p give about 1 meV higher values for the R-acoustic mode, compared with PBE [59].

Finally, we compare the experimental data for the dispersion of the two R modes with the theoretical predictions based on the SCP method in Fig. 9. The INS data for the R-tilt mode compare very well with the theoretical data, while in the IXS measurement only one extra data point could be resolved. In the direction R-M theory predicts two branches but both the INS and the IXS measurements could only resolve one branch, as discussed earlier. The R-acoustic mode is also very well reproduced by both the INS and IXS data. A systematic offset is visible, but as discussed above this is most likely due to the use of PBE in the theoretical calculations.

V. THEORETICAL RESULTS: ATOMIC DISPLACEMENTS

A. Mean-squared displacements

The mean-squared displacement (MSD) $\langle (u_i^{\alpha})^2 \rangle$ can be obtained within the HP and SCP models using Eq. (2). It can also be obtained directly from MD simulations making a time

FIG. 10. Mean-squared displacements from MD, SCP, and HP, based on PBE. Experimental data taken from Levin *et al.* [20], Perrichon *et al.* [17], and Knight [5].

average along the MD trajectory

$$\langle \left(u_i^{\alpha}\right)^2 \rangle = \langle \left(u_i^{\alpha}(t)\right)^2 \rangle_{\text{time}},$$
(9)

where $\mathbf{u}_i(t)$ is the displacement of atom *i* from its equilibrium position \mathbf{R}_i^0 , i.e., $\mathbf{r}_i(t) = \mathbf{R}_i^0 + \mathbf{u}_i(t)$. The obtained results for the mean-squared displacements (MSDs) are shown as function of temperature in Fig. 10. In the same figure we also show experimental data for BZO from Refs [5,17,20].

We notice that for barium and zirconium all directions are symmetrically equivalent. Barium has a larger displacement compared with zirconium due to its considerably weaker interaction with its surroundings. On the other hand, the displacement for oxygen is strongly anisotropic, with larger displacements perpendicular to the Zr-O bond.

Consider first the HP model. At 0 K the MSD is given by its zero point motion value. It increases with temperature and at high temperatures it approaches its classical behavior, i.e., linear in temperature.

In the SCP model anharmonicity is included. There is a clear difference between SCP and HP at higher temperatures for the oxygen motion perpendicular to the Zr-O bond. The FCP-based SCP potential energy landscape is stiffer than the harmonic (HP) one (cf. Fig. 2) and thus leads to smaller displacements. The displacements for barium show a similar effect but less pronounced.

In the MD model the motion is treated classically. Therefore, at low temperatures the displacements approach zero. This is seen in Fig. 10. Furthermore, if the system is harmonic the MSD increases linearly with temperature. This is obtained for the zirconium motion and the motion of oxygen parallel to the Zr-O bond. However, for the motion of oxygen perpendicular to the Zr-O bond the slope of the MSD decreases when the temperature increases, due to the motion being anharmonic. The same behavior is observed for the barium motion but less pronounced.

The difference between the MD and the SCP models is that the latter includes the quantum fluctuations of the atomic motion, while MD does not take those into account. On the other hand, MD includes the full anharmonicity in Fig. 1, while SCP does that in an approximate way. From Fig. 10 we note that MD and SCP agree quite well at 300 K for all atomic motions except for the oxygen motion parallel to the Zr-O bond. For this high-frequency motion, quantum effects are sizable even at 300 K.

We can also compare with available experimental data. In Fig. 10 data at 5, 10, and 300 K from Perrichon *et al.* [17], Knight [5], and Levin *et al.* [20] are added. The mean-square static disorder has been subtracted from the raw data by Knight [5]. We notice that theory and experiments compare quite well. However, the data by Levin *el al.* [20] for Zr are systematically larger and the 300-K data point for oxygen parallel to the Zr-O bond by Perrichon *et al.* [17] deviates significantly from the rest of the experimental data.

B. Mean-squared relative displacements

The fluctuations in the distance between two atoms in a crystal can be measured using extended x-ray absorption fine structure (EXAFS) spectroscopy [60]. This technique gives a more local information about the fluctuations of the atomic positions compared with the mean-squared displacement (MSD), measured by x-ray and neutron scattering.

The *R*-tilt mode with its essentially rigid antiphase tilts of the ZrO₆ octahedra should be visible as large fluctuations of the nearest-neighbor Ba-O atomic distance. Indeed, Lebedev and Sluchinskaya [61] found large values of the Debye Waller factor for the Ba-O atomic pairs using EXAFS at 300 K. Usually, the Debye-Waller factor in EXAFS monotonically increases with increasing interatomic distances, but Lebedev and Sluchinskaya [61] found a significantly larger value for the first shell (Ba-O) compared with the second (Ba-Zr) and third (Ba-Ba) shells (cf. Table I). They attributed this to the appearance of a structural instability and speculated in the possible formation of a structural glass state in BZO as the temperature is lowered.

Granhed *et al.* [59] showed, using DFT calculations, that the low frequency of the *R*-tilt mode gives rise to an "anomalously" large value of the Debye-Waller factor for the Ba-O atomic pairs. The study by Granhed *et al.* [59] was based on the harmonic approximation for the lattice vibrations and several exchange-correlation functionals within DFT were used.

TABLE I. Parallel mean-squared relative displacements (MSRDs) from MD, SCP, and HP, in units of 10^{-3} Å², based on PBE. Compared with experimental data taken from Lebedev and Sluchinskaya [61].

	<i>T</i> (K)	Expt.	MD	SCP	HP
$\langle \Delta u_{\parallel}^2 \rangle_{\rm BaO}$	0			6.4	6.8
	300	14.5	18.2	17.5	22.5
$\langle \Delta u_{\parallel}^2 \rangle_{ m BaZr}$	0			2.1	2.2
	300	6.8	7.5	7.2	8.2
$\langle \Delta u_{\parallel}^2 \rangle_{\mathrm{BaBa}}$	0			2.7	2.7
	300	8.7	12.3	12.0	13.5

Here, we consider the effect of the anharmonicity which was neglected in Ref. [59]. The parallel mean-squared relative displacement (MSRD) between neighboring atoms a and b can be obtained from the phonon eigenvectors and frequencies according to [60]

$$\langle \Delta u_{\parallel}^2 \rangle_{ab} = \frac{1}{N_q} \sum_{\boldsymbol{q},\nu} \frac{\hbar}{2\mu_{ab}\omega_{\boldsymbol{q},\nu}} |Y_{\boldsymbol{q},\nu}^{ab}|^2 \coth\left(\hbar\omega_{\boldsymbol{q},\nu}/2k_{\rm B}T\right), (10)$$

where

$$Y_{\boldsymbol{q},\nu}^{ab} = \left[\left(\frac{\mu_{ab}}{m_b} \right)^{1/2} \mathbf{e}_{\boldsymbol{q},\nu}^b e^{i\boldsymbol{q}\cdot\mathbf{R}_{ab}^0} - \left(\frac{\mu_{ab}}{m_a} \right)^{1/2} \mathbf{e}_{\boldsymbol{q},\nu}^a \right] \cdot \hat{\mathbf{R}}_{ab}^0 \quad (11)$$

and $\mu_{ab} = m_a m_b/(m_a + m_b)$ is the reduced mass, \mathbf{R}^0_{ab} is the vector connecting the equilibrium positions of neighboring atoms *a* and *b*, and $\hat{\mathbf{R}}^0_{ab}$ is the corresponding vector of unit length. Equations (10) and (11) can be used to obtain the parallel MSRD within the HP and SCP approximations. The parallel MSRD can also be directly computed from MD simulations by making a time average of the expression

$$\langle \Delta u_{\parallel}^2 \rangle_{ab} = \langle | [\mathbf{u}_a(t) - \mathbf{u}_b(t)] \cdot \hat{\mathbf{R}}_{ab}^0 |^2 \rangle_{\text{time}}$$
(12)

along the MD trajectory [60].

Our resulting parallel MSRDs are presented in Table I using PBE. In the harmonic approximation (HP) we indeed get a large value for the nearest-neighbor Ba-O atomic distance at 300 K, considerably larger than the experimental value. That was also noticed in Ref. [59] and explained by the underestimation of vibrational frequencies in PBE. If we add anharmonicity and evaluate the MSRD within the SCP and MD approximations the value is reduced but still larger compared with experiments. This reduction is due to the stiffer potential energy surface (PES) when anharmonicity is included, and hence smaller displacements. Similar trends, but much less pronounced, are obtained for the nearest-neighbor Ba-Zr and Ba-Ba atomic distances.

Still, the values including anharmonicity, i.e., the SCP and MD values, are larger than the experimental values. However, using improved approximations for the exchange-correlation approximations within DFT we expect the agreement to be improved. It was shown in Ref. [59] that inclusion of Fock exchange as implemented in the two hybrid functionals, HSE [38,39] and CX0p [40], stiffens the atomic bonds and thus increases the vibrational frequencies. It then follows that the MSRD will decrease.

FIG. 11. The potential energy surface (PES) along the *R*-tilt mode based on PBEsol. The double-well minimum potential indicates a structural phase transition in the classical limit.

VI. DISCUSSION

A. Exchange-correlation functional

As a compromise between accuracy and computational cost we have based our computations on the PBE functional (see Sec. II A). The vibrational properties at the R point are quite sensitive to the exchange-correlation approximation used in the DFT calculations [17]. To test this sensitivity, we have also computed the temperature-dependent vibrational spectra using the PBEsol functional.

A fourth-order FCP is constructed based on the PBEsol functional (for details, see Supplemental Material [47]). In Fig. 11 we show the FCP result for the PES along the *R*-tilt mode FCP model together with the DFT data. In contrast to PBE, the PBEsol functional shows a weak double-well landscape for the *R*-tilt mode potential. This means that the *R*-tilt mode is unstable in the harmonic approximation with an imaginary frequency, in this case, equal to 4.2i meV. This implies that, in a classical description and using PBEsol, the cubic phase for BZO is unstable close to 0 K.

The FCP based on PBEsol is used in the same way as described for PBE to obtain the temperature-dependent phonon frequencies. In Fig. 12 we compare our theoretical results using the two different functionals, PBE and PBEsol. The frequencies based on the PBEsol functional are about 2 meV lower compared with the PBE frequencies and PBEsol gives a somewhat stronger temperature dependence. Both functionals give rise to a finite frequency at T = 0 K. For PBEsol, which has a double-well landscape for the *R*-tilt mode potential (see Fig. 11), it is worth noting that quantum fluctuations at T = 0 K stabilize the cubic structure using the SCP model.

B. Effect of quantum fluctuations

To demonstrate the effect of the quantum fluctuations of the atomic motion on the R-tilt mode we can now compare the result for the SCP model using the amplitude in Eq. (4), which contains the proper quantum fluctuations, with the results

FIG. 12. Theoretical temperature dependence of the *R*-tilt mode based on PBE and PBEsol, respectively. The SCP-cl model shows the effect of neglecting the quantum fluctuations of the atomic motion in the SCP method. The HP is the harmonic approximation.

obtained by using the classical limit of the amplitude, i.e.,

$$A_{\lambda}^{i,\text{cl}} = \sqrt{k_{\text{B}}T/(m_{i}\omega_{\lambda}^{2})}.$$
(13)

The latter model is here denoted SCP-cl and neglects the quantum fluctuations. When lowering the temperature SCP-cl starts to deviate from SCP around 100 K, as seen in Fig. 12. The frequencies decrease more rapidly compared with the SCP model and for PBE the frequency approaches the PBE harmonic frequency value of 3.8 meV, the HP value. However, the SCP-cl value for PBEsol approaches zero at a finite temperature. Hence, by neglecting quantum fluctuations, PBEsol predicts an unstable cubic structure at 0 K.

C. Thermal expansion

We have neglected thermal expansion in our theoretical analysis. In Ref. [17] thermal expansion within the quasiharmonic approximation was taken into account for the frequency of the *R*-tilt mode. The PBE value for the frequency increased by 0.8 meV in the temperature interval 0 to 300 K, while the increase for the two hybrid functionals HSE and CX0p was less, about 0.5 meV, in the same interval. Therefore, the temperature dependence derived here may increase slightly if thermal expansion is taken into account.

D. Comparison with other work

Recently, Zheng *et al.* [27] considered anharmonic lattice dynamics in BZO with focus on thermal transport in the temperature range 300–2000 K using the PBE functional. They used a nonperturbative self-consistent phonon method as implemented in ALAMODE [26,62]. They also investigated the *R*-tilt mode and they obtained a frequency increase from 6.3 to 8.2 meV in the temperature range 0 to 300 K (see their Fig. S4.). This can be compared with our present SCP results using a similar theoretical approach. We find an increase from 5.6 to 9.0 meV in the same temperature range. This difference can likely be attributed to the difference in the FCPs used in the two different works (cf. the discussion in Ref. [63]).

Here a $4 \times 4 \times 4$ supercell was used to train the FCP, whereas Zheng *et al.* used a $3 \times 3 \times 3$ supercell incommensurate with the *R*-tilt mode. Furthermore, Zheng *et al.* constructed the harmonic force constants separately from the anharmonic force constants. These differences in the FCP construction likely explain the observed difference in calculated frequencies.

VII. CONCLUSIONS

We have presented a combined experimental and theoretical study of the temperature dependence of the antiferrodistortive *R*-tilt mode in barium zirconate (BZO).

Our inelastic neutron and x-ray scattering measurements on a single crystal clearly show that the antiferrodistortive phonon mode at the R point softens substantially, from 9.4 meV at room temperature to 5.6 meV at 2 K. In contrast, the barium-associated acoustic mode at the same R point is found to be nearly temperature independent.

We use a first-principles computational approach to study the lattice dynamics. A force constant potential (FCP) including cubic and quartic anharmonic terms is derived using training structures from density functional theory (DFT) calculations. The PBE functional is employed for the exchange-correlation functional and to gauge the sensitivity with respect to the exchange-correlation functional, the PBEsol functional is also used in some calculations. The vibrational motion is investigated by direct molecular dynamics (MD) simulations as well as by using a self-consistent phonon approach. The effect of the anharmonicity on the lattice dynamics is hence taken into account nonperturbatively.

Our theoretical approach, based on a self-consistent phonon approach, predicts a soft phonon mode at the *R* point, associated with antiphase tilt oscillations of sequential oxygen ZrO_6 octahedra, with a strong temperature dependence, from 9.0 meV at 300 K to 5.6 meV at 0 K, in great agreement with the present measurements. The quantum fluctuations of the atomic motion are found to be important to obtain the proper temperature dependence at low temperatures. To accurately describe the vibrational motion at low temperatures it is thus important to include both anharmonicity and quantum fluctuations of the atomic motion in a consistent way.

The mean-squared displacements of the different atoms are determined as function of temperature and are shown to be consistent with available experimental data. The meansquared relative displacements have also been computed. These displacements are measured in EXAFS and the fluctuations of the Ba-O distance are a sensitive local measure of the antiphase tilt oscillations of the oxygen octahedra. We compare our computed values for the fluctuation of the Ba-O distance with available EXAFS data at 300 K and the agreement with the EXAFS data is improved when anharmonicity is taken into account in our theoretical modeling.

Altogether, our work provides a robust description of the lattice dynamics and its temperature dependence at the R point, but future work will be needed to clarify open questions on the lattice dynamics away from R. This includes the exact position and temperature dependence of the tilt branch along the R-M direction, as well as a proper deconvolution of the inelastic spectrum. The temperature evolution of the line shape in INS spectra still needs to be understood and the importance of different ingredients evaluated (resolution effects, anharmonicity, potential presence of nanodomains, etc.). We anticipate that further inelastic scattering experiments or diffuse scattering will help to address this issue and that extended computational modeling may uncover the presence or absence of the proposed nanodomains.
